7. Finally, there is a close relationship between the physical exercise practised and degenerative changes in the heart, arteries, and the kidney, or the cardiovascular renal system, when the voluntary and the involuntary muscles are not kept in tone by regular systematic physical exercise, particularly in later life to old age.

428 Forty-seventh Street.

AUSCULTATORY PERCUSSION.

By A. L. BENEDICT, A.M., M.D., F.A.C.P.,
BUFFALO.

The comparatively slight use of this method may be explained as follows:

1. The sceptic explanation that those of us who use it are the victims of self deception and that we secure correct results by the law of chance of adherence to normal standards or the detection of abnormalities by evidence of other methods suggesting to us what we think we determine by auscultatory percussion.

2. Those liberal enough to concede that genuine information may be secured by this method, suppose it to require special delicacy of auditory perception or skill.

3. Many are prejudiced against it, as against various other procedures, by the extravagant claims of some of its advocates.

4. Many set it aside after brief trial because they themselves or others whom they follow as expert authorities fail to acquire the technique. It is not realized that although the general principles involved are the same as for any other diagnostic method based on hearing, it can not be acquired and judged like a mere novel detail of ordinary percussion or of auscultation, but requires considerable experience and practice, even if one be skilful or has a good medical reputation or both.

The acceptance of the first explanation would terminate the discussion as soon as begun, but the writer may say candidly that he has frequently argued with himself as to the propriety of holding any opinion against which there is good authority, has checked the method at necropsies by driving bank pins into the body wall to show the results of auscultatory percussion, at operations by outlining organs immediately before section, by comparing results by this method with those by fluoroscopy and radiography, and in various other ways. In the great majority of instances, the method has proved reliable, even when the results seemed so improbable that failure was conceded in advance. For instance, in a test on a rotten cadaver, the diaphragmatic division of thoracic and abdominal organs was made out, but the liver could not be located except as an incredibly narrow zone. On section, in spite of the obvious obstacles, it was found that the liver had actually been correctly mapped out. In another case, repeatedly examined, auscultatory percussion consistently failed to locate the lower portion of an easily palpable liver. At necropsy, it was found that the apparent failure of auscultatory percussion was really a brilliant success, as it had located accurately the hepatic tissue, while the palpable, lower portion of what was considered the liver, consisted of almost pure cancerous tissue. In other instances, failures have proved to be due to jump-

ing at plausible conclusions. For instance, what at first thought were considered a large stomach and a small liver, both of unusual shape and position, were soon analyzed, in conjunction with ordinary percussion and other signs, as transposed organs. In general, auscultatory percussion cannot designate an organ, it merely shows that there is, in a given location, something that has essentially the same vibratory conduction, and whether this is a certain organ or a part of an organ or a pathologic mass of some kind is merely a matter of induction. Two practically identical units, closely opposed, may vibrate as a unit; for example, the stomach and distended colon, two tumors, etc. Sometimes, for reasons that cannot be explained in detail, ordinary auscultatory percussion may reveal such conditions as a single unit, while auscultation of the vibrations of a tuning fork or electric buzzer, may distinguish them.

The second explanation, that peculiar delicacy of hearing and skill are requisite for the successful use of auscultatory percussion, does not seem warranted. While, of course, one may distinguish differences of pitch and quality in listening to percussion or some other source of vibrations with the stethoscope, just as he may by the ear alone, it is better to disregard these altogether and to concentrate the attention on the fact that the sounds transmitted are essentially identical so long as the stethoscope and the source of vibrations are over the same vibratory unit and that a sudden change occurs when either passes the limits of this unit. When we reflect that carpenters, even amateurs, use essentially the same method to determine the location of scantlings in walls in order to secure a proper place for nails, it is obvious that the method is not particularly difficult. But, as mentioned under the fourth explanation, considerable practice is necessary to acquire the art, say two or three months of preliminary experiment before relying on it, and expertness in other diagnostic methods and prestige, genuine or self-accredited, cannot relieve one of the necessity of study.

The third explanation, that of extravagant claims producing scepticism, is somewhat difficult of discussion. Various extravagant claims, as that one could split a dollar bill, fly in a heavier than air machine, locate internal organs by sight, eliminate typhoid fever, have proved to be true, while on the other hand very modest claims consisting of mere extensions and modifications of well-established diagnostic methods have proved to be false. So much depends upon the personal equation that the extravagance of a claim can be defined only in the light of practical results. So far as the writer is concerned, he will admit the possibility of error for every test and, on the other hand, claim that this admission conduces to greater aggregate accuracy. From the writer's standpoint, one of the most extravagant claims made for auscultatory percussion is that it can locate the spleen. There is no *a priori* reason why it should not do so and it often does, but, in general with a small spleen, not necessarily closely apposed to the body wall, one is extremely liable to map out the posterior projection of the stomach or the splenic flexure. On one occasion, a friend had me shut my eyes and apply the stethoscope to the back while he percussed over the front of the chest. For the moment he made me think that he could discriminate the different pulmonary lobes, something that I had attempted but of whose impossibility I had long ago become convinced. It transpired that he was a sceptic, and that he was simply fooling me by a skillful adaptation of the well known possibilities of bone conduction. It is obvious that one deceiving himself by such a procedure could very well make an extravagant claim that would discredit the whole method.

General Principles and Limitations.—1. As stated above, differences of pitch and quality should be disregarded and attention should be paid merely to the abrupt change in loudness or otherwise, indicating that the limits of a structure vibrating as a unit have been passed.

2. It follows, unless the method is worked out along different lines, to detect differences in pitch and quality, that auscultatory percussion gives no information of nature of an organ or mass, much less of the identity of an organ. All such conclusions must be induced from information otherwise obtained.

3. Two factors determine the vibration of a given area as a unit, make-up and solidarity. The term make-up is deliberately chosen instead of some such term as structure in order to avoid misunderstanding. For example, the collapsed stomach, while of the same structure as the distended organ, does not vibrate as a distinguishable unit. When collapsed, the splenic flexure of the colon naturally tends to fill in the space and, unless one takes pains to determine the condition by ordinary percussion, swallowing tests, etc., one is very likely to jump at the conclusion that the splenic flexure is the stomach. Gas above liquid gastric contents, of course, shows as a different area. A consolidated portion of lung, though, in a sense, not departing from its original histologic structure, is obviously very different in make-up, so far as the transmission of vibrations is concerned, and hence will be mapped out as an independent unit, by auscultatory percussion. The case of the cancerous liver mentioned above is another example of difference in make-up. Bones have practically identical structure, with certain well known qualifications, but two bones though giving nearly or quite the same note on ordinary percussion, are entirely shut off from each other by auscultatory percussion, unless, of course, they are normally or pathologically united by bony formation, as in the skull or sacrum or a firm ankylosis. Normally, vibrations will be conducted the whole length of a bone, from percussion point to stethoscope, providing, of course that these two points are chosen so as to provide fairy direct application. If the bone is fractured, such conduction will not occur, unless the fracture is only partial or the fragments are so firmly in apposition, as in impaction, that solidarity persists from the practical standpoint. As implied above, virtual solidarity may occur from the close apposition of two similar vibrating units, as the stomach and distended colon. The same qualification applies occasionally to closely apposed tumors, and it is conceivable that an intraligamentous or other cyst, with thin walls, might vibrate as a unit with an ascites, though in several cases, with the help of other signs and general hints the writer has been able to distinguish. For instance, a sur-

geon was about to inject air to treat a supposed tuberculous peritonitis, but, mainly by auscultatory percussion, it was demonstrated that the condition was an intraligamentary cyst. It frequently happens that a tumor of the gastric wall can be shown to be of different nature from the stomach as a whole, though, in case of quite general cancerous infiltration, no such discrimination is possible. A stomach with open and infiltrated pylorus, plus dilatation of the duodenum was diagnosed as hour-glass stomach. In such a case, the error is one of inference rather than of failure of auscultatory percussion. In this particular case, the same error of inference was made even after *x*-ray examination, but this was several years ago, before *x*-ray technique was well developed and the condition of the pylorus prevented the appearance of a typic duodenal cap, so that the same error might be made today.

4. In comparing auscultatory percussion with *x*-ray pictures of rapidly moving parts, as the heart and the stomach, there is an obvious difference, as the latter method gives instantaneous pictures, while the former is necessarily slow and gives only average data. The cardiac area as determined by auscultatory percussion corresponds to the actual anatomic appearance more closely than does the radiogram, probably for the reason that the latter is usually taken at an angle and that some parts of the heart do not "take" on the plate. In one instance, auscultatory percussion showed a normal stomach, whereas the Roentgenologist diagnosed hour-glass contraction and showed a most convincing picture. The writer was almost convinced of a blunder until the Roentgenologist offered confirmatory evidence consisting of more plates. Unfortunately these showed the hour-glass contraction at different sites. Fluoroscopic examination was then made and this showed where the trouble lay. We had to deal with a stomach of marked peristaltic contractility but of normal area and without hour-glass contraction. In such cases it is obvious on reflection that radiograms rather exaggerate the depth of the wave. Not only does the bismuth ride on the inner surface of the stomach, but on top of rugæ, and it is quite possible that a rapid contraction further exaggerates the indentation by throwing the contents of the stomach, including the bismuth, away from the mucosa. Similarly, diaphragmatic movements are exaggerated by the fluoroscope or contrasted inspiratory and expiratory radiograms, especially if we watch or compare the anterior and posterior rib shadows, whereas in auscultatory percussion we usually deal with shallow respirations and average the location of the supradiaphragmatic and infradiaphragmatic organs in the slower process of percussing and marking.

5. The body-wall inevitably transmits vibrations and modifies those from deeper seated organs. Thus, granted that there is no particular vibratory unit under the stethoscope, one can still imagine himself mapping out an organ, but its suspiciously regular circular outline and diameter of about 1½ inches prevent error—as in the case of transposition of the heart, when the stethoscope and percussion are applied as usual.

Auscultatory percussion also requires that the vibrations transmitted by the finger—or by any modification, as the end of a pencil, a dental plugger with rubber disk fixed on the end, a tuning fork with hard rubber base, or a similar terminal from an electric buzzer, the elastic strips advocated by Abrams for a somewhat different use, etc.—be applied where the particular organ or mass is fairly near and firmly applied to the body wall, and also that the stethoscope receive the vibrations with similar restrictions as to directness of conduction, the requirements for the latter being more definite.

The vibrations conducted from the organ to the stethoscope necessarily radiate in the superficial tissues so that a thick body wall exaggerates the actual size of the organ.

Empirically, rather than for demonstrated scientific reasons, satisfactory conduction from the organ requires a stethoscope end not much smaller than the ordinary cardiac end. The finger tips, with or without pleximeter finger interposed—and mediate percussion is usually more distinct though requiring assistance in holding the stethoscope—as well as the terminals of the various substitutes for finger percussion, also have an appreciable size. Thus, it is obvious that the results of auscultatory percussion can not be marked out as lines in the geometric sense but can only approximately be limited in bands of, say, a centimeter in minimum diameter. Such demarcation is sufficient for clinical purposes, but does not and cannot approach the requirements of those who demand statements in millimeters. Whether these demands can be complied with by other methods may also be disputed. Generally speaking, an organ or mass of less than 2 inches in diameter cannot be satisfactorily dealt with by auscultatory percussion, though one may, of course, determine the continuity or fracture of a bone of much less diameter in one direction.

It may be remarked in passing that many physicians fail to note an important fallacy of palpation, as contrasted not only with auscultatory percussion but ordinary percussion. Anything, the liver, for example, palpated through the body wall, is felt as a mass considerably larger than it really is. Pinch up the abdominal wall, divide its double thickness by two, and one gets a pretty good idea of the fallacy of palpation. Failure to note this obvious precaution accounts for the very common diagnosis of large liver, when the organ is of normal size or even moderately diminished in bulk.

While, theoretically, the vibrations transmitted to an organ are conducted throughout its entire extent, there are limits to the size of an organ or mass which can be mapped out practically by auscultatory percussion, and these limits depend somewhat on the conductivity of the organ or mass itself. Fortunately, limitations along these lines do not interfere seriously with practical needs. One cannot map out the whole of a normal lung, but there is no need of doing so. The liver probably transmits vibrations throughout its whole extent, on account of its greater density, but toward the dome there is a greater and greater intervening depth of lung, so that one can neither get vibrations to nor from it, and practically the normal boundaries by auscultatory percussion are from about the fourth rib or space to the costal arch, but its departure from the costal arch in either direction is usually significant of its actual bulk. As the stomach is practically never fully distended and would

present the same difficulties as the liver if it were, it typically appears as a more or less regular elipse, normally inclined at an angle of 45 degrees to the horizontal but tending toward the horizontal or vertical position according to well known circumstances. The spleen is usually not adapted to auscultatory percussion unless enlarged so that it can be better mapped out by papation. The heart is usually pretty satisfactorily mapped out by auscultatory percussion. The kidneys are too deeply seated and the appendix too small for this method. The colon is seldom anything like uniformly distended and usually only part of the transverse portion can be mapped out, while it is, of course, out of the question that we should attempt to outline its whole course. The same applies *a fortiori* to the small intestine, though a distended area may be mapped out and the procedure may be of practical value in distinguishing intestine from other organs or masses. Abdominal tumors and ascitic collections, on account of the conductivity of their contents, are practically never too extensive for satisfactory determination, but the inaccessibility of deeper portions leaves much to the imagination, as in other forms of physical examination, while small tumors are adapted to auscultatory percussion only when near the anterior or lateral abdominal wall. The pelvic organs are out of reach. In the case of the lungs and pleural cavities, auscultatory percussion is of value mainly to determine the boundary between supradiaphragmatic and infradiaphragmatic contents when, for various reasons, ordinary percussion and auscultation fail. But any local condition affording a contrast to surrounding parts may usually be located and its nature inferred or established by other methods. For example, a consolidated area of lung of reasonable size, a collection of fluid, a good sized cavity, a pneumothorax, with or without contrasting liquid, may usually be located as something decidedly different from juxtaposed contents, and even this information is a great help in making a diagnosis.

377 Elmwood Avenue.

NASAL CAUTERIZATION IN THE TREATMENT OF CERTAIN CHRONIC AFFECTIONS (METHOD OF PIERRE BONNIER).

By A. LEPRINCE, M.D.,

NICE, FRANCE.

SURGEON LARYNGOLOGIST, ST. ROCH HOSPITAL.

In July, 1907, Dr. Pierre Bonnier presented to the Paris Neurological Society a communication entitled "Reflex Enteritis of Nasal Origin." In this note he showed that since the roots of the trigeminus cover the whole extent of the bulb, an explanation may be found in their manifold connections, normal or individual, of the great variety of bulbar reflexes which may have their origin in even a slight irritation of the nasal mucosa.

The majority of the nervous centers situated in the region of the oblongata are the guardians of our organic integrity and functional equilibrium. Their rôle is fundamental, physiologically, pathologically, and therapeutically. We all remember Claude Bernard's experiment. It was one of the achievements of Dr. Pierre Bonnier, whose death last spring threw the whole of the French scientific world into mourning, to show that the oblongata may be reached through different points of the mucous membrane of the nose and that it is possible to penetrate to all parts of the bulb by way of the descending root of the trigeminus.

It is by acting on these nervous centers through the fibers of the trigeminus, which extend throughout the nose, that it is possible to repair their functional activity. The works of Pierre Bonnier on "Centrotherapy" have made it possible to establish plainly enough the different zones of the nasal mucosa which correspond to the various bulbar centers.

A slight cauterization of the inferior turbinal or of the septum will cure an enteritis, a nervous disorder, a cardiopathic condition, an asthma, bladder troubles, etc.

This method of cure, which at first may appear paradoxical, is in reality nothing more than an isolated case of that general centrotherapy which was practised by physicians of old, and notably in Chinese medicine (cha-chin). The method is a rational one since it acts directly on the bulbar center, which gives the nervous influx to the organ affected.

Every illness originates primarily in a nervous element and it is only logical to attack that part of the oblongata which is to some extent the center in which is organized the nervous defense of our principal functions: digestion, circulation, nutritive changes, internal secretions, etc.

The present war, said Dr. Bonnier in one of his latest communications to the Société de Biologie (March 4, 1916), has made apparent the nervous disturbances resulting from the acute, anxious, and prolonged nervous tension exacted of the thousands of men whose lives have been changed overnight. Failure of the bulbar nervous system has led to interminable cases of gastroenteritis, asthma, cardiac affections, affections of the bladder, albuminuria, phobias, neurasthenia—in short a mass of troubles which rapidly have become chronic through breakdown of the nervous system and in which treatment is directed only to the peripheral and local results instead of to the stimulation of the bulbar regulator which alone will reestablish the normal function of the organs affected.

As one of Dr. Bonnier's disciples, I will simply bring to the attention of the readers of the Medical Record a few recent observations on treatment and the results obtained in various conditions of nasal cauterization, exclusive of all other forms of treatment.

Case I.—Mme. H., æt. 58. The blood pressure was 20. There was ringing in ears. After three cauterizations the blood pressure was lowered from 20 to 18 and the tinnitus aurium was lessened.

Case II.—M. D., æt. 60. Had suffered from hemorrhoids for 30 years. Nasal cauterization was done on April 2. On May 6 the hemorrhoids were greatly diminished in size. Four further cauterizations were required before a favorable result was obtained. At the present time the hemorrhoids can easily be pushed in and they no longer bleed. Bowel motions are no longer painful.

Case III.—Mlle. D., æt. 17. Erythromelalgia of the extremities. The hands and feet were always icy cold and reddened; the nose also was red and cold. Two cauterizations cured the coldness and redness of hands and feet. Two further treatments put an end to the coldness and redness of the nose.

Case IV.—M. L., æt. 19. Erythromelalgia which commenced three years ago following chilblains. The first cauterization was done on May 18, and the second on May 24. The cure which resulted from these two treatments has persisted to this day.

Case V.—M. D., æt. 25. Albuminuria and general weakness. Since June, 1916, after several courses of treatment for Bright's disease, he was excreting regularly 2 grams of albumin to the liter. Since then he has been on a milk diet. Suffered from depression and general fatigue and was obliged to sit down constantly. This patient was cauterized for the first time on December 21, and within a day or two the sense of fatigue was lessened. Four cauterizations considerably improved the general condition. By January 25, the patient's weight had increased by 7 kilos, and for the previous fifteen days he had given up dieting and had eaten meat, partaking of the same food as his comrades. The quantity of albumin in the urine had not changed, being still about 2 grams to the liter.

Case VI.—M. L., æt 61. Localized facial neuralgia (tic douloureux). Even slight pressure on the right incisors provoked an attack of neuralgia and violent pain in the superior dental branch. It was impossible for the patient to chew his food without pain and he lived on vegetables only. Having consulted Dr. Petit, surgeon-dentist, in order to have the painful incisors taken out, the latter referred him to me and on the same day, March 23, I gave him a nasal cauterization. This immediately provoked pain. By March 25, however, there was manifest improvement in the neuralgia and pain was caused only by vigorous brushing of the teeth. The evening of the day the cauterization was done, the patient was able to eat bread and meat, which he had not done for several weeks. When seen again on April 10, this patient considered himself quite recovered, the pain having completely disappeared since March 25.

Case VII.—B., æt. 42, an army officer, had suffered from left-sided sciatica since the winter of 1916-17. He had been treated with electricity, hot air, and massage, without appreciable result. Experienced pain after walking, the pain radiating from the ileum. There was no pain along the course of the nerve, no wasting of the calf muscles, and no obliteration of the gluteal fold. Nasal cauterization was done on Jan. 21, 1919. Two hours after the cauterization, pain developed in the loins and lasted for three days. By the 24th, the lumbar pain had disappeared and at the same time the sciatica had improved. On the 25th, the patient was able to walk without difficulty and could easily lift his leg when the knee was extended.

Case VIII.—M. D., æt. 50. Had suffered from tabes for 15 years. There was tinnitus aurium, with lightning pains. After three cauterizations the noises in the ears had disappeared and the patient could easily stand upright with eyes closed and without vertigo. There was no improvement in the lightning pains or in the insomnia from which he had suffered.

Case IX.—Mme. O. D. Complained of tinnitus aurium and deafness, the former being very marked and isochronous with the pulse; the blood pressure was 21. The first cauterization lowered blood pressure to 17; a second brought it down to 16. Treatment which was commenced in March, 1918, necessitated six cauterizations. From April 27, the date of the last cauterization, the tinnitus, which had been increased during the night following application of the cautery, became progressively less until it completely disappeared. This patient, the mother of a physician, had been unable to sleep and had become neurasthenic to the last degree.

Case X.—Mme. M., æt. 39. This patient was deaf and had tinnitus; Romberg's sign was present. Bone conduction was greatly diminished. The watch could not be heard when in contact with the ear. Nasal cauterization on March 24. On the 26th, watch in contact with ear could be heard, as could also the note *la* on the tuning fork at a distance of 10 cm. A second cauterization improved the tinnitus slightly and cured the Romberg.

Case XI.—M. P., æt. 23 (military patient). Had suffered from urethritis and prostatitis for 12 months. There was pain in the loins with a sensation of weight in the lower abdomen, with fatigue and general depression. Patient had been losing weight for a year. There were signs of pulmonary tuberculosis. The first cauterization was done on Saturday, January 17, and was followed by immediate improvement which was noted the following day. On that day the patient danced all the afternoon without fatigue. The prostatitis was greatly improved and the general sense of fatigue had entirely disappeared. This case is still under treatment.

Case XII.—M. M., æt. 25. Liver affection contracted in the Congo. Could take only kephyr and yoghourt; any other food caused immediate vomiting. Patient suffered from profound neurasthenia, abulia, tic, acne, nightmares every night, and general depression. Was cauterized on January 13, and from the 15th improvement was noted by the patient himself, who commenced to eat normally without vomiting. On the 17th, a second cauterization was done; this was followed by liver disturbances and nightmare. On the 25th, the patient had gained 3 kilos, and was bright and had begun to show interest in life. His nightmares had disappeared entirely, the acne was improved, and the neurasthenia was completely cured.

Case XIII.—D. K. Suffered from habitual constipation, enteritis, gastric stasis, and palpitation of the heart. Patient was cauterized on December 24 and had a bowel movement the same evening, two motions the next day, and from that time on a stool regularly every day. Three cauterizations definitely cured the enteritis and stopped the palpitation.

Case XIV.—V., æt. 45. Suffered from general wasting, digestive trouble, vomiting, and constipation. Had lost 4 kilos in 2 months and could take only milk. Radioscopic examination revealed no lesion. Cauterization done on December 4. The same evening there was rumbling in the abdomen and regular bowel movements occurred on the four succeeding days and then arrest again on the fifth day. Two further cauterizations were done and by December 15 the patient had gained 200 grams. He was again cauterized on December 22 and 28 and on January 4, 12, and 17, and gained respectively 200 grams, 400 grams, 300 grams, and finally 600 grams. At the present time he is able to eat meat and bread, and to walk without fatigue, and considers himself almost cured.

Case XV.—Mme. B. Suffered from tinnitus aurium, paludism, and habitual constipation. The tinnitus was cured by two cauterizations, the constipation was greatly improved after the first, and from the time of the second cauterization the bowel movements became regular.

Case XVI.—Mlle. B., æt. 35. Symptoms: Tinnitus and coldness of extremities. Had suffered from enteritis for 15 years, with obstinate constipation. The coldness of the extremities and the enteritis were cured by three cauterizations, since which time the patient has had regular bowel movements each day. The tinnitus has not been improved.

I have purposely chosen these few cases from a large number of similar ones in order to show the diversity of the chronic affections in which nasal cauterization may be applied.

It will be noted that certain patients were improved and others cured by the first cauterization and that in other cases again it was necessary to apply the cautery several times before obtaining any result.

Although the nasal topography has been carefully explained by Bonnier, and although the exact zone in which the fine point of the galvanic cautery should act can usually be determined, it is none the less true that the chief difficulty is to touch the right spot, since the anatomy of the nose and the distribution of the nervous filaments vary in individuals, and, indeed, it may be said that no two noses are alike. However this may be, one may be assured, as a rule, of good results in from 72 to75 per cent. of cases treated.

A source of error to be avoided lies in cauterizing the mucous membrane too deeply. The slightly reddened cautery should be applied lightly so as just to graze the surface sufficiently to provoke a very slight burn, which should no longer be apparent at the end of forty-eight hours. Severe burns produce no result, while those which are too superficial often affect only the mucosa and do not produce the necessary reflex. This is a matter of dexterity and practice which, however, can easily be acquired.

The employment of cocaine is useless and often leads the operator to cauterize too deeply. I use it only when it is necessary to reduce the size of an enlarged turbinate, when it is a question of cauterizing its posterior extremity, an operation that must be done under control of the sight.

Certain sceptical physicians have refused to see in similar statistics or in those presented by Bonnier, anything more than fortunate cases or have attributed the cures obtained to suggestion. They are certainly happy suggestions which in eight days can cure an enteritis of fifteen years' standing, hemorrhoids which have existed for twelve years, a neurasthenia of several years' duration, lower blood pressure, etc.

"Life is an incessant struggle on the part of our organism against internal and external causes of death. We know very little about the way in which our organism carries on this struggle, but our nervous system knows, and the oblongata is the great regulator of our functional equilibrium. Let us study these, for it is not the doctor who works the miracle," said Bonnier, "but Nature herself."

Medicolegal Notes.

Insufficient Evidence of Negligence.—In an action against two physicians for negligent treatment of a fracture of the tibia of the left leg of the plaintiff, a woman 49 years of age, it appeared that the defendants, on being sent for on November 5, 1916, reduced the fracture and placed it in a fracture box in the ordinary way with Buck's extension, attaching a weight of 26 pounds thereto. On December 19 the apparatus was removed by the defendant V., a part of the weight having been taken off a week previously. At the time of the removal of the apparatus, V. attempted to ascertain whether or not union had taken place, but desisted on account of complaints made by the plaintiff. He advised the plaintiff to use her leg. He called again on December 27 and then discovered that there was no union of the ligaments. He then advised an operation for the purpose of fastening the ends of the bones together. Plaintiff was then taken to a hospital, where another doctor performed an open operation and fastened the bones together by means of a Love splint. The plaintiff remained in the hospital for 10 weeks and then went home. The bone was united perfectly but her left ankle was stiff as a result of the long disuse. Negligence was alleged in the following respects: (1) The application of the weight of 26 pounds; (2) the direction to use the injured leg; (3) failure to inspect the leg for about 8 days after removing the apparatus; (4) failure to take an *x*-ray picture of the broken leg up to the time of removal to the hospital. Judgment for the plaintiff was reversed for the following reasons:

An expert medical witness for the plaintiff testified: "If the bones had been held somewhat apart, there generally still is an attempt at union. In other words, nature would attempt to repair the broken fragments. It would send out callus, and, if that can reach across, why, it might go together." All the medical testimony, including that of this witness, showed that there are a certain percentage of cases in which nature makes no effort to unite the fragments, and there was no dispute that this was the situation in this case. The medical testimony showed further that there may be such a failure of nature in cases where absolutely correct treatment has been given and correct methods followed. There was no evidence to show that there was any greater stiffening of the ankle at the end of the seven weeks' period, when the extension was removed, than should be expected in cases of this character. Upon the trial it was stated that no claim was made of any negligence at or subsequent to the time of the removal of the plaintiff to the hospital, and that, on the contrary, the services of the doctor there were entirely proper and satisfactory.

It was held to be established by the overwhelming weight of evidence in the case that the claimed negligence had nothing to do with the failure of nature to commence the healing process. If there had been a proper amount of exudate, and it appeared that the failure of the ligaments to unite was due to the fact that the ends could not be united, a different situation would have been presented; but there was not a syllable of such testimony in the case. The failure of nature to commence a healing process is sometimes due to one cause and sometimes to another, and sometimes no cause whatever can be assigned. It seemed to the court purely and wholly speculative to say that the nonunion was due in any degree to the negligence of the defendants.

There was no evidence to show that the bones were not properly placed in apposition to each other, or that the weights were not properly attached in the usual and customary way. If an expert cannot say that the treatment was improper, upon what ground can the jury arrive at that conclusion? The fact being established that there was no union, it was apparently assumed that it must be due to some negligent treatment. The evidence did not sustain that view. The entire case rested upon the testimony of a physician that he would have treated the fracture in another way. Physicians are not compelled to choose at their peril between two accepted methods of treatment. Statements of experts that they would have treated the fracture in some other way are incompetent. —Staloch v. Holm, 100 Minn. 276, 111 N. W. 264. The whole evidence was that there was no ankylosis, properly so called, of the ankle joint, but the stiffened condition of the plaintiff's foot was due to failure to use it and to a shortening of the cords, which could be remedied by use or by a simple operation.

There was no *x*-ray apparatus available at the time of the injury; and it did not appear that, had an *x*-ray picture been taken during the treatment, it would have shown that no callus was being formed at the point of fracture. It was therefore held that the failure to procure an *x*-ray during the course of treatment did not amount to negligence or unskilful treatment.—De Bruine v. Voskuil, Wisconsin Supreme Court, 169 N. W. 288.

Basis of Expert Opinion.—In an action to recover damages for an alleged illness caused by tonsilitis claimed to have resulted from traveling in a "cold passenger car" on the defendant's railroad, a medical witness was permitted to give a detailed history of the plaintiff's case as related to him by the plaintiff. This witness was permitted to testify as follows: "Q. State to the jury, in your opinion, from what Dr. Plummer (the plaintiff) described to you, whether that condition could have been produced by exposure on that train? (Objection by defendant.) A. It is perfectly possible from the history that he gave me, and highly probable.

On appeal from a judgment for the plaintiff, it was held the objection should have been sustained. The form of the question permitted the witness to decide the very question submitted to the jury upon the statement which the witness had received from the plaintiff. It permitted the expression of an expert opinion based upon facts related by the plaintiff to the witness, although the truth of the facts had not been passed upon by the jury. The opinion of an expert cannot be based upon an assumption of the truth of facts related to him by a witness or any third person. The expert opinion must be based upon the assumption that the fact submitted to the expert has been established by the verdict of the jury.—Plummer v. Seaboard Air Line R. Co., North Carolina Supreme Court, 96 S. E. 1032.

Military Medicine.

Tetanus at the Battle of the Piave.

Tizzoni, writing in the *Giornale di Medicina Militare* for December 31, gives the statistics of the cases of tetanus in the troops and prisoners of war in connection with the Battle of the Piave. The latter, which included the period of the Austrian offensive and Italian counteroffensive, appears to have lasted from June 1 to June 30, and the number of cases of tetanus to develop in this period was 71. During the month of July there were 13 additional cases not included in the summary. Of the 71 cases 9 occurred in Austrian prisoners. Contrary to what would be expected not all of the cases resulted from war wounds, the total under this head being but 53. Other causes were injuries not received in battle, injuries probably self inflicted, and surgical operations. The latter numbered 2 while 3 malingerers gave themselves the disease through attempts to produce artifacts in the skin. The number of cases from strictly accidental wounds was 4. The incubation periods were unlike those commonly published by reason of the large percentage of late tetanus due in part perhaps to serum prophylaxis. Thus of the 53 strictly military cases the incubation period was more than 10 days in 36. In 17 cases the incubation was over 15 days. While this is longer than cases in civil practice it seems to have been normal in military practice for 12 days has been given as the average with 21 as the maximum in British figures. In the author's material the individual period has varied from 1 to 73 days with an average of 13 days. Of the 53 military cases with some kind of antitoxin prophylaxis but 15 were lost, a mortality of less than 30 per cent. If, however, we select only cases which received full immunizing doses in season the mortality becomes vanishingly small. In previous figures in which the use of preventive serum was standardized the mortality was 5.8 per cent. Standardization means the use of a single approved serum in repeated injections at a sufficiently early period after the receipt of the wound.

An Epidemic of Icterus Observed in Roumania during the Campaign of 1917.—In a paper read before the Paris Academy of Medicine last fall, Professor Cantacuzene of Bucharest gives an account of the epidemic of icterus described by other observers in Roumania in 1918, and which appears to have been similar to that which occurred in the Dardanelles campaign. It began in the army in May, 1918, and spread through it with startling rapidity. It was distinguished by its wide extension and remarkable benignity. The epidemic reached its acme in August and disappeared in October.

Cantacuzene states that the disease began with slight fever, falling after the first or second day, then appeared nausea with or without vomiting, and with tenderness over the gall-bladder; the conjunctivæ showed jaundice and then the skin generally; asthma was pronounced; other symptoms were muscular pains chiefly in the legs, pale stools in half the cases, pruritus in a third, infrequent pulse, urine rich in biliary pigments and in urobilin. The attack lasted from 8 to 15 days. Later the cases were less typical. Massive fatty degeneration of the liver was found in the rare cases of death which occurred, due to primary angiocholitis of the intralobular biliary canaliculi.

Neither by the microscope nor by inoculation into guinea-pigs were spirochetes ever discovered. Blood culture was positive in a third of the cases and yielded atypical paratyphoid bacilli. The author concludes that these atypical paratyphoid bacilli are probably the pathogenic agents of epidemic jaundice, and this view was supported by the following experiment: Eight of ten young men vaccinated against typhoid and paratyphoid more than six months previously, swallowed an agar culture 24 hours old of one of the atypical paratyphoid strains; two received each one-tenth of the culture intravenously. The latter had no symptoms whatever. Of the eight who ingested the culture one had a rise of temperature of 1.5°; six had slight fever lasting one or two days, followed by jaundice of the conjunctivæ with nausea and tenderness over the gall-bladder; one presented after four days the complete syndrome with generalized jaundice and was ill for a fortnight.

Conference on Rehabilitation of the Disabled.—The first International Conference on Rehabilitation was held in New York City from March 18-21 inclusive, under the auspices of the Red Cross Institutes for Crippled and Disabled Men and for the Blind. The French and Belgian Ministers of War, the Italian Ministry of Pensions and Labor, and various departments of the Canadian Government, were represented. The American agencies which sent men or women are the office of the Surgeon General, the Army, the Federal Board of Reeducation, and the Bureau of War Risk Insurance. Dr. Maurice Bourrillon, president of the permanent inter-allied committee on war cripples, and director of the French National Institute for Crippled Soldiers, described the beginnings of the making over of 694,000 Frenchmen incapacitated by war diseases or wounds, and stated that France had remade and reeducated 45,767 broken men. Louis Alleman, chief of the educational staff of the institute for cripples at Port-Villez, France, spoke for Belgium; Vittorio Putti, director of the Rizzoli Institute at Bologna, for Italy; Miss Ethel Wood, secretary of the War Pensions Committee, for England; and F. Gerald Robinson and W. E. Segsworth of the Department of Soldiers' Civil Reestablishment for Canada. Dr. Charles A. Prosser, director of the Federal Board of Vocational Education, in telling of the scope of America's plans for rehabilitation, said that about 200,000 men in this country would need training. Nearly 40,000 have already registered with the Federal Board asking for help. A closing mass meeting was held on Sunday afternoon, March 23, at the Hippodrome, with Charles E. Hughes presiding.

Convalescent Soldiers Sent to California.—A fully equipped hospital train left the Grand Central Terminal in New York, on March 24, for southern California. It carried about 135 sick men and a number of convalescents from the debarkation hospitals at Fox Hills, Staten Island, the Grand Central Palace, Greenhut's, and the hospital at Camp Mer-

ritt. It will make the transcontinental journey without a break. In addition to ward cars there will be a car fitted out as an operating room. The train is in charge of the Medical Department of the United States Army.

Major Amputations in United States Forces.—According to official advices from Washington, the total of major amputations to date is 3,034, of which approximately 600 are arm amputations and 1,708 leg amputations. The remaining 726 are of hands, feet, and two or more fingers. Not all of the men who suffered these mutilations require special training to enable them to make a living.

Surgeon General Honors Base Hospital No. 2.—Major General Merritt W. Ireland, Surgeon General of the Army, has addressed a letter to the trustees of the Presbyterian Hospital, New York City, in which he commends the work done by Base Hospital No. 2, the Presbyterian Hospital unit, which was among the first of the Red Cross base hospitals sent to France. The letter earnestly recommends that measures be taken to "keep the organization of the unit intact, and that every effort be made to imbue its future personnel with the fine *ésprit* to be expected in the possessors of the glorious heritage of splendid achievements handed down from the great war by the original personnel of Base Hospital No. 2." Special attention is invited to the excellent work done by Colonel George E. Brewer as director of Base Hospital No. 2.

Casualties Among American Medical Officers.—The casualties among American medical officers in France from the time of the arrival of the first units to March 13, 1919, numbered 442. Of these, 46 were killed in action, 22 died of wounds, 12 died of accident and other causes, and 101 of disease; four were lost at sea, seven were reported as missing in action, and 38 were taken prisoner. Two hundred and twelve were wounded in action.

Volunteer Medical Service Corps.—The Central Governing Board of the Voluntary Medical Service Corps held its final meeting, prior to the termination of its war-time activities, on March 14. The report submitted by Dr. Edward P. Davis, president of the corps, shows that nearly 70,000 applications have been received from physicians for membership in the corps, of which 56,540 were received and coded prior to the signing of the armistice, November 11, 1918. Qualifications of these civilian doctors, classified and coded on cards, will be placed in the library of the Surgeon General of the Army, where they will be accessible to all governmental departments for all time to come. In commenting upon the service rendered by the Voluntary Medical Corps, Dr. Davis says that when one considers the burden thrown upon the medical profession by the conditions created by the war and the influenza epidemic, he does not think any profession has met a similar crisis as nobly as did the medical profession, and that no small part of the moral value and success of the profession was due to this corps. About 13,000 doctors, whose applications for membership in the Voluntary Medical Service Corps were received before the armistice was signed, but which were not acted upon by their State committee, will receive letters from Dr. Davis giving the reasons why their membership could not be completed by furnishing them with the visible evidences of their tender of services, that is, the insignia and certificate of the corps. The offer of services and qualifications, however, have been transferred to permanent code cards, which are to be preserved.

Major Simon Strauss, recently in charge of a surgical service in General Hospital No. 1, New York, has been honorably discharged from the U. S. Army, and has resumed private practice at 440 West End Avenue.

Dr. Roy A. Douglas of Huntington, Tenn., and Dr. Alexander J. Gillis of Baltimore have been decorated with the Military Cross by the British Government for bravery and distinguished services in the war.

Dr. Mary H. Elliott of Holly Springs, Miss., has sailed with the medical mission to Servia, under the auspices of the Red Cross.

No Soldiers both Armless and Legless.—In refutation of a widely circulated report that there were many so-called "basket cases," that is, soldiers without either arms or legs, in the military hospitals, Surgeon General Ireland has issued a statement declaring that he has personally examined the hospital records, and is able to say that there is not a single "basket case" among the American soldiers, either on this side of the Atlantic or among the Expeditionary Forces.

Memorial Hospital in Rheims.—Mrs. Benjamin Lathrop, director of the American Fund for French Wounded, in France, announces plans for an American memorial hospital in Rheims. This city has been chosen as the site for the hospital because it is in the heart of the district where are buried the American men who lost their lives in the fighting. The city of Rheims is donating a site of 16,000 acres, and Americans are to build the hospital, at a cost of about $100,000. The size of the hospital will, however, depend upon the number of beds endowed. Six thousand dollars will endow a bed for all time.

Deaths in the Service.—Capt. WILLIAM CLARENCE GATES, M. C., U. S. Army, of Bucyrus, Ohio, a graduate of the University of Michigan, Ann Arbor, in 1890, died from lobar pneumonia in the base hospital at Vichy, France, on February 21, aged 50 years. He was for several years chief surgeon of the Calumet and Hecla Mining Company, Calumet, Mich., and founder of the Crawford Hospital, Bucyrus.

Lieut. WILFORD WAYNE MARTIN, M. C., U. S. Army, of Kirksville, Mo., a graduate of the Eclectic Medical University, Kansas City, in 1903, aged 41 years, was thrown from his horse and killed instantly while on duty with the American Expeditionary Forces in France on December 4.

Lieut. WINFIELD MARCH WHITE, M. C., U. S. Army, of Sioux City, Iowa, a graduate of the State University of Iowa, Iowa City, in 1912, aged 29 years, on duty with the American Expeditionary Forces in France was killed in action at Bazancourt, France, on November 4.

Lieut. CHARLES HAIGHT HOLCOMBE, M. C., U. S. Army, of Trenton, N. J., a graduate of Jefferson Medical College, in 1901, died at his home on March 5, aged 51 years.

Lieut. WILLIS BENJAMIN HARRISON, M. C., U. S. Army, a graduate of the University of Buffalo, N. Y., in 1916, aged 27 years, died from pneumonia at Silver Creek, N. Y., on February 4.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

ETIOLOGY AND PATHOGENESIS OF LOCALIZED TETANUS OF THE EXTREMITIES.

TETANUS localized in the limbs is uncommon and if one carefully examines the recorded case-reports it at once becomes evident that many of the diagnoses are subject to suspicion. For example, in a case of Bruns' the affection was a generalized tetanus during convalescence from which paraplegic phenomena developed. The same applies to a case reported by Gilbert and Lereboullet, which began with tetanus and contracture of the neck, and at the time of recovery left sequels localized in the lower limbs. The etiological circumstances of the localized forms of tetanus are commonplace, the point of inoculation in civil life usually being the foot, though it may be elsewhere, in two reported cases being near the elbow. The main fact to be retained is that in cases of localized contractures the point of inoculation is always seated on the limb involved. In these infrequent cases how can the localization of the contractures be explained? In animals an injection of the tetanic toxin produces local spasms in the first place and the phenomenon becomes generalized only secondarily and this upon the condition that the dose injected be sufficient. The evolution is ascending.

Generally speaking, in man the evolution of the process would lead one to suppose that the centres are the first to be involved since trismus and contracture of the neck open the drama, while the trunk and limbs are involved only ulteriorly. Therefore, the evolution is descending in progress. Now, in man as in animals the nerve trunks are undoubtedly directly sensible to the action of the toxin and when patients are questioned the local onset of the disease is frequently fleeting. It is well known that shooting pains starting from the wound and localized cramps are prodromal signs of tetanus. If this first localized phase, which in animals is of some duration and therefore easily observed, is fleeting in man it is because of the hypersensitiveness of the centers in reference to the tetanic toxin; the cord reacts almost immediately and the evolution is as if it had been the first involved. When, as occasionally happens, the toxin is in too small a quantity or too attenuated to become diffused throughout the organism and impregnate the centers, the peripheral nerve impregnation may alone manifest itself and the result will be a localized tetanus.

Four reasons engage us to admit this theory of localization due to hypovirulence of the bacillus and to hypoinfection. Firstly, because in many cases the point of inoculation rapidly cicatrizes and therefore does not allow a long period of bacterial culture to ensue. The importance of this argument must not, however, be exaggerated, because it is well known that even minute excoriations of the limbs give rise to rapidly fatal generalized tetanus. Secondly, several authentic cases have been reported where an antitetanic injection had been given after the wound had been received and must have contributed not a little in attenuating the infection. Thirdly, localized tetanus is usually mild in character and offers a chronic symptomatology, and death very rarely ensues. Fourthly and lastly, the auto-observation of Nicolas, published by Chauveau, has the value of an experiment. During some experimental work Nicolas pricked the thenar eminence with a needle infected with an inappreciable dose of tetanus toxin. Following this inoculation tetanus developed, beginning in the thumb and remaining localized there for two days and then progressively invading the forearm, arm, spinal muscles, and lastly the muscles of mastication. The condition was serious, the contractures became general and recovery did not take place until the lapse of two months.

It is difficult to explain by this theory those cases which, in the first place, are localized and become generalized secondarily and may even terminate in death. Is it to be supposed that in these cases the toxin continues to be elaborated in the focus of infection and ends by attaining the centres, or that the latter, being at the beginning immunized by a prophylactic injection or otherwise, end by losing this immunization? Such is possible, but doubt remains. Perchance these cases may be explained by a tetanic reinfection at the site of the wound in a subject relatively immunized, as was not long since maintained in a discussion at the Academy of Medicine of Paris, but if it be admitted that the localized forms of tetanus are benign in nature on account of a mild virulence of the bacillus inoculated, it is not proved that this slight virulence alone can explain the localization.

AS TO ACCLIMATIZATION.

THE question of the acclimatization of the white man in the tropics has given rise to somewhat wide divergencies of opinion and to a great deal of discussion. As a rule, authorities on the subject, that is medical men who have lived for lengthy periods in tropical countries, attribute the ill health from which white men suffer after some time spent in these climates to an injudicious diet or to transgressing certain laws of health. However, even on the matter of diet, there is no universal agreement, for while most of those who have gained practical experience state that less protein and little alcohol should be taken, others and among them the late Col. Charles

Woodruff declared that a generous meat diet should be eaten and that alcohol should be by no means barred. This divergence of views is commented on by two Dutch observers, C. D. de Langen and H. Schut, who think (*Tropical Bulletin*, January 15, 1919) that the literature on acclimatization of the white man in the tropics leads nowhere, but reveals "a number of hypotheses in chaotic disorder without proof and without a leading idea being manifest in the various considerations." The authors point out that there is a real difference between the blood of Europeans in the tropics and at home. Such are the deflection to the left of Arneth's index as shown in the Philippines and Australia and the coast of Africa, and the difference in blood pressure demonstrated by Kiewiet de Jonge, who showed that the maximum blood pressure of natives in the Dutch Indies was lower than that of the Europeans and that the maximum blood pressure of Europeans does not diminish after even quite prolonged tropical residence.

As for blood sugar Dutch investigators have shown that the quantity of reducing substances increases in Europeans after residence in the tropics and have also noted the large quantity to be found in natives and animals. They disagree with the conclusions of McCay (*Indian Journal of Medical Research*, July, 1916), who found the value of blood sugar in Bengalis to be 50 per cent. higher than the figure for Europeans, but did not test Europeans in Calcutta, and therefore attributed the excess in natives to diet rather than climate. It is held by de Langen and Schut that the increase of blood sugar cannot be attributed to parasitic disease, for it occurs very soon after arrival, nor to change of food. In their opinion it must be ascribed to the climate *per se*, especially to the temperature and not to the intensity of light, for in the mountainous districts of Java one gets a lower figure, although the rays are much stronger than at the lower altitudes. They regard it as quite certain that the quality of blood sugar is largely dependent on the suprarenal glands and that their function is regulated by the sympathetic system. Schut shows that the injection of substances stimulating the sympathetic system is followed by an increase of sugar in the blood and a decrease of liver sugar. The authors show that in tertian malaria a rise of temperature is preceded by a rise in the blood sugar, a hyperglycemia which falls again before the fall of temperature. The authors hold that when the European arrives in the tropics, blood sugar at once begins to increase; the superfluous sugar will then appear in the urine, or be got rid of by combustion.

Thus may be explained the "low fever" of the tropics. The hyperglycemia disposes to neuritis and polyneuritis, beriberi, as well as to invasions of the tubercle bacillus. For these reasons the authors advise that diabetics, persons with a tendency to renal glycosuria and tuberculosis, and sympathicotonic persons should be absolutely dissuaded from settling in the tropics, at any rate in the lowlands.

THE SUTURE OF LARGE INJURED BLOOD VESSELS.

THE suture of large blood vessels, such as the brachial, femoral, and popliteal arteries and veins, after injury by projectiles of war, was carried out successfully many times and by many operators during the present war, and is a resource which will undoubtedly be employed in civil practice to a much greater extent in the future than has been customary heretofore. The usual resource, except in cases where the injury is slight and the hemorrhage may be controlled by packing, is ligation; and this is very apt to be followed by gangrene. Unfortunately, occasion for suture of such vessels sometimes arises in civil practice through accidental injury in the course of operation, as well as after gunshot or stab wounds or through other injuries. The materials needed for repair are quickly available in any first class hospital, the technique is fairly simple and easily mastered by any competent surgeon, and the results can hardly be worse and may be much better than when ligation is practised. We feel, therefore, that the simple rules laid down by Major Charles Goodman in the November number of *Surgery, Gynecology and Obstetrics* will well bear repetition.

After referring to five cases of suture of the femoral or popliteal vessels, all of which were successful, Goodman calls attention to the fact that failures in many of the reported cases may have been due to neglect of one or more of the essential points of the operation, namely: (1) A high degree of asepsis; (2) the segment of vessel to be sutured must be freed from all macroscopic blood and properly protected from all contact during the suture; (3) The sutures must not be introduced under too great tension; (4) Thrombosis is favored by bacterial infection and by the tissue juices and their ferments. The lumen of the vessel to be sutured should, therefore, be thoroughly washed with Ringer's or saline solution, followed by liquid paraffin. Sutures introduced under tension may cut out and induce hemorrhage. Goodman therefore says that the technique of a vascular suture should consist of the following steps: (1) A free exposure of the injured vessel. (2) A temporary occlusion of its lumen above and below the lesion, either by flexible clamps, serrefines, or tape. (3) A thorough perfusion of the intervening segment with Ringer's solution or saline solution followed by liquid paraffin. (4) A removal with scissors of the adventitia encroaching on the line of suture. (5) Silk sutures threaded on fine cambric needles and sterilized in liquid paraffin should be introduced through both media and intima, carefully avoiding the adventitia. (6) A deep vessel, requiring repair, may be rendered more accessible by lifting the vessel from its sheath upon two narrow ribbons. This procedure may entail a division and ligation of one or more of the branches which hold the vessel in the normal anatomical position. (7) A walling off of the remainder of the wound with pledgets of black silk

will assist materially in safeguarding the line of suture from thrombokinase, and will also serve to make the delicate white sutures more easily seen by the operator. (8) When a main artery is completely severed, a circular suture should not be attempted unless the severed ends can be approximated without tension. When this is not possible, a segment of vein can be transplanted, or, when such a procedure is not practical, a paraffined tube may bridge the gap and maintain the blood supply until an enlarged collateral circulation is established. The tube should then be removed.

If the technique outlined above is rigidly followed many limbs will undoubtedly be saved which would otherwise have to be sacrificed because of gangrene following ligation of the injured vessels.

Mobilization After Joint Injuries.

It may come to pass as a result of the experience gained by surgeons during the war that views as to the treatment of joint lesions will be very considerably revised. Mr. J. W. Dowden, writing in the *British Medical Journal* of November 23, 1918, states without reserve that owing to the practice of immobilizing joint lesions of all kinds thousands of British soldiers have been rendered cripples for life, who, had they been treated without the use of splints or with splints used for only a short time and with the aid of physical therapy in various forms, at the present time might have the use of their limbs. In a special number of the *U. S. Naval Medical Bulletin*, in a report on medical and surgical developments of the war by Dr. W. Seaman Bainbridge, the question of immobilization of injured joints is referred to. Dr. C. Willems, who was in charge of the Belgian Military Hospital and part of the Military Hospital at Bourbourg, like Mr. Dowden, did not believe in the efficacy of prolonged immobilization and was one of the first to abandon this mode of treatment. Bainbridge embraced the opportunity afforded him of visiting the hospitals over which Willems presided and of observing his methods and the results thereof at close range, and was immensely impressed with their value. Willems' system of treatment is based on the principle of immediate active mobilization of the joint. He points out, however, that in order to obtain the best results certain general rules must be adhered to. The motions must be carried out by the patient himself; they must involve those muscles ordinarily used in moving the joint; they must be begun the moment that the patient comes out of the anesthetic; they must be carried out to the point of their maximum excursions, and they must be as nearly as possible continuous. They should not be supplanted by or combined with passive motion. These motions cause practically no pain unless they produce displacement of a large fragment of bone, in which cases such movements are contraindicated. Of course, the details of the treatment vary considerably, according to the nature, extent, and location of the injury. Dowden is in agreement with Willems so far as the harmfulness of prolonged and ill-judged immobilization is concerned and states emphatically that adhesions are frequently caused by prolonged immobilization. However, he appears to differ somewhat from Willems in that he advises passive movement of the joints and muscles at first and active mobilization as soon as possible. Both these surgeons are at one with regard to the necessity for mobilization in the treatment of joint lesions and are agreed as to the perniciousness of prolonged immobilization. The experiences of the war have crystallized these views in both.

Neurasthenia as a Self Limited Affection.

That endogenous neurasthenia comes and goes as it lists is a fact well enough known to the initiated, under which term we include those who have been life long sufferers from it. That it resists all treatment including psychotherapy has not been generally conceded because at times it appears to yield to psychic factors such as good fortune and change of environment and whatever can benefit from such factors should be favorably influenced by suggestion. Bernheim, however, writing in *Le Progrès Médical* for January 18, confesses that it is in no wise amenable to this influence and always runs a predestined course. Whenever a psychic factor appears to have arrested it, this is but a coincidence, for said factor came into play only at the end of the period. Whether there is a simple form of neurasthenia which is a pure neurosis does not fully appear from the author's statements. At times he seems to imply that this is the case and that neurasthenia is divided about equally between ordinary and paradoxical forms. The type to which he refers and which has been very common since the war is largely postinfectious and due to some organic affection of the medulla which has resulted from the toxin of the disease. This form can be isolated from the simple type by objective phenomena like exaggerated tendon reflexes not seen in the latter. It follows, however, from what the author says that conditions which have heretofore been called neurasthenia are often something else, as psychasthenia or mild melancholia. Another peculiarity of the self-limited type is the participation of the gastroenteric system. The presence of an organic substratum explains why these patients recover at a definite time and without treatment. It is interesting to note that this master of suggestion toward the close of his long career has been forced to conclude that neurasthenia, or at least part of it, cannot be reached by psychotherapy save in a few superficial symptoms. He implies either that neurasthenia is two fold in its nature or that such neurasthenia as is amenable to suggestion merits some other name and is only neurasthenoid. The theory of an organic postinfectious or toxic substratum does not explain the recurrences of neurasthenia.

News of the Week.

Red Cross Conference at Cannes.—Announcement is made from the headquarters of the American Red Cross in Washington that the majority of the invitations to attend the conference of experts to be held at Cannes, France, beginning April 1, to prepare a program to relieve suffering and combat disease in the general interest of humanity have been accepted. Experts will be present from France,

England, Italy, Japan, and the United States. Among the Americans invited to be present are the following: Dr. William H. Welch, Dr. Simon Flexner, Dr. Hermann M. Biggs, Dr. E. R. Baldwin, Dr. Theobald Smith, Dr. Wycliffe Rose, Col. George Walker, Col. Homer Swift, Col. William F. Snow, Dr. L. Emmet Holt, Dr. Samuel McHamill, Dr. Fritz B. Talbot, Dr. Livingston Farrand, Major William Palmer Lucas, Col. Richard B. Strong, Assistant Surgeon General N. S. Cummins, Col. F. F. Russell, and Col. Lindsay R. Williams.

A Mosquito Museum.—The Army Medical Museum in Washington is making a collection of mosquitos representative of all species at camps or posts where United States troops are stationed. Collections are to be made at each station at least bi-weekly at three periods during the twenty-four hours; such observations will determine the time when the insects are most prevalent at each locality.

Child Welfare Conference.—The Department of Labor is planning a conference on child welfare to be held in Washington during the week of May 6, under the auspices of the Federal Children's Bureau, to which men and women qualified to speak regarding the war's lessons on the health, education, and work of children have been invited. A number of foreign guests are expected. After the conference in Washington a series of regional conferences will be held at convenient centers throughout the country during May and June.

Annual Meeting of Home for Hebrew Infants.—The twenty-third annual meeting of the Home for Hebrew Infants, New York, was held at the home on March 23. The chief speakers were Dr. Henry Larned Keith Shaw and Dr. Alfred F. Hess. It was announced that during the past year Dr. and Mrs. Alfred F. Hess had contributed a special ward to the home at a cost of $2,500.

Hospitals Want a Voice in Legislation.—The Hospital Conference of the City of New York, representing forty of the largest institutions in the city which maintain nurses' training schools, has appealed to John Finnegan, acting Commissioner of Education, for a hearing on the proposed legislation affecting the hospitals. This conference was called because several bills have been introduced into the Legislature during the past few years which, if passed, would revolutionize the training of nurses in the hospitals. At present there is an amendment to the nursing bill at Albany which provides, among other things, for the training of short-term nurses or attendants. The hospitals feel that there is a demand for this class of attendants, but since the hospitals will be given the training of these students they feel that they should be consulted in the matter. Hitherto they have been ignored.

Money Needed for Tuberculosis Work in France.—A plea is being made by the Paris Committee for Edith Wharton's War Charities, which is cooperating with the French Government, for money with which to carry on tuberculosis work. The French Government has urged this committee to carry on the work for two years until it is in a position to take it over. To support the work $400,000 is needed. Two friends of the organization have promised $100,000 if the remainder could be obtained. The Red Cross has already contributed 200,000 francs, 300 beds and their equipment, and two laboratories.

A Loop-hole in Narcotic Drug Law.—James A Hamilton, Commissioner of Correction of New Yor City, attacks the law respecting the sale of drug on physicians' orders to drug addicts. He find that there is nothing to prevent a physician fron using the unofficial prescription form authorizin the sale of small quantities of drugs to individual several times a day. A physician might write sev eral prescriptions for lawful quantities for each pa tient, who could have each prescription filled at different drug store. Against this "repeating," Commissioner Hamilton points out, there is onl the good faith of the physician, and he adds, the la does not define "good faith."

New Public Health Order in England.—Th Local Government Board of England has enacte an order which went into effect on March 1, makin notification of malaria, dysentery, trench feve acute primary pneumonia, enteric fever, relapsin fever, and typhus fever, compulsory. The report o cases of these diseases will be followed by immed ate investigation of the sources of infection. In th case of trench fever, malaria, or dysentery believe to have been contracted in the United Kingdom th health officer must notify the Local Governmer Board and arrange for the reception of the patie in a suitable hospital, unless he is satisfied tha treatment at home can be carried out with all pr cautions necessary to prevent the spread of th disease. In cases of malaria the health officer wi provide the necessary mosquito netting, quinin treatment, and proper advice on treatment to pr vent relapses. In cases of dysentery the health off cer may notify the person attacked that he or sh must discontinue any occupation connected wit the preparation or handling of food or drink fo human consumption, and that children in the charge must not attend school. In trench fever th health officer may order the segregation of all th inmates of the building until they and their clot ing have been rid of lice. The Local Governme Board will shortly issue a circular which will b distributed country wide giving details of the r sults obtained in various localities regarding ce tain recommendations for the prevention and cu of influenza. While measures for preventing a outbreak have so far proved unsuccessful, certa measures for preventing the spread of the disea have proved satisfactory in a number of district

Smith Drug Bill Defeated.—Governor Smith bill recommending that the recently created Sta Commission of Narcotic Drugs be abolished and i functions transferred to the New York State D partment of Health was refused release from co mittee by the Assembly on March 27. The Sena took similar action on the bill about a week pr viously.

Examine Medicines for Alcohol.—The Assemb Excise Committee on March 28 reported to the Ne York Legislature the bill which gives to the Sta Excise Commission authority to enforce througho the State whatever legislation Congress may ena for the enforcement of the prohibition amendme to the United States Constitution. An amendme which this bill carries creates a committee consi ing of three doctors and two druggists to pass up the 250 medicines now on the market and determi whether they are beneficial, harmless, or intoxic ing.

Mr. Horace Fletcher, known through his strenuous advocacy of prolonged mastication of food, who died in Copenhagen on January 12, left a large sum to Harvard University, the income to be used by the university for "fostering a knowledge of healthful nutrition" and to offer the Horace Fletcher prize for the best thesis on the subject, "Special Uses of Circumvallate Papillæ and the Saliva of the Mouth in Regulating the Physiological Economy of Nutrition." The gift is in recognition of the services and sympathy of Prof. Henry Bowditch Pickering and Prof. William James to the cause to which Mr. Fletcher devoted his life.

Expenditures of the Rockefeller Foundation.—The Rockefeller Foundation has announced its budget for 1919, which disposes of its income of $6,750,000 during the coming year. Of this sum, $2,367,130 will be for public health and $3,726,594 for medical education. The public health activities will consist chiefly of efforts against yellow fever, tuberculosis in France, malaria, and hookworm. The yellow fever commission, headed by General William C. Gorgas, will sail shortly for Central and South America. The commission on tuberculosis will continue its work in France on a large scale at the request of the French authorities. Demonstrations showing how to control malaria will be carried on in two of the Southern States, and a campaign against hookworm will be waged in twelve States in America and in twenty-one foreign states and countries. Appropriations have also been made for studies in mental hygiene and public health at Johns Hopkins University and for the development of public health nursing. Additional expenditures have been authorized for the Rockefeller Institute for Medical Research and toward a contribution of $1,000,000 made two years ago for the development of the medical school of the University of Chicago.

Dr. A. L. Stone has been appointed health officer of Waltham, Mass.

Dr. Jacob Goldberg of Buffalo has been appointed a member of the Public Health Council of the New York State Department of Health, to succeed Dr. Wilhelm Gaertner, whose term had expired.

Amendments to Sanitary Code.—At a meeting of the Public Health Council of the New York State Department of Health, on January 10, regulation 36 of chapter 11, in reference to the quarantine of infectious diseases, was amended by the insertion of the following paragraph: "Typhoid or paratyphoid, if the patient's occupation involves the handling of milk, dairy products, or other food, until all signs of the disease, or secondary or complicating infections incited by the agents of these diseases, have disappeared, and until two successive specimens of the intestinal discharges of the patient have been taken at an interval of not less than seven days, and have been examined in a laboratory approved by the State Commissioner of Health and found to be free from typhoid or paratyphoid bacilli." Regulation 13 of Chapter 111, relating to the delivery of milk and cream has been amended to read: "Such milk must be delivered within thirty-six hours after pasteurization between April 1 and November 1, and within forty-eight hours after pasteurization between November 1 and April 1, and such cream within forty-eight hours after pasteurization, unless a shorter time is prescribed by the local health authorities. The resolution regarding the qualifications of public health nurses which requires that these nurses shall be twenty-one years of age and registered at the time of their appointment, was repealed. Regulation 6-a, a new regulation on shaving and lather brushes, was added to the code. This reads: "No shaving or lather brush shall be manufactured or offered for sale or used unless the hair or bristles thereof shall have been so treated for the purpose of destroying anthrax germs as to conform with the regulations of the State Commissioner of Health. These regulations took effect on March 1, 1919.

Course in Public Health Administration.—The Training School for Public Service of the New York Bureau of Municipal Research, in cooperation with the Public Health Committee of the New York Academy of Medicine, announces a six weeks' course in public health administration from April 30 to May 2 inclusive. The course will include a series of conferences on public health and administration, conducted under the leadership of men and women who are recognized authorities in the public health field, and field study and observation of public health agencies and institutions in New York City. This part of the program will begin on May 26 and continue until June 7, and will be arranged to suit the convenience and interests of special groups of students. A fee of $25 will be payable on registration. Not more than fifty will be enrolled and preference will be given to public health executives. The conferences will be held at the New York Academy of Medicine. Further information may be obtained by addressing Dr. Carl E. McCombs.

Lynn, Mass., Doctors Raise Fees.—At a conference attended by fifty physicians of Lynn, Mass., on March 15, a new schedule of fees was adopted which went into effect on March 15. Under the new rates house calls are $3, office calls $2, confinements $25, and night calls, between the hours of 10 P. M. and 7 A. M., $5. In adopting these rates the statement was made that the poor of the city need have no apprehension about their individual inability to meet the new schedule. In the future as in the past the services of the profession would be at the demand of any worthy person in the community.

Bill to Aid Tuberculous Poor.—Senator Julius Miller has introduced a bill into the New York State Legislature providing State and county aid for poor persons afflicted with tuberculosis. Senator Miller points out that according to the Health Department statistics there were on January 1 of this year 32,048 tuberculous cases in New York City, with hospital or institutional accommodations for only a pproximately 5,000. The Miller bill provides that the expense of care of poor tuberculous patients be borne, one-third by the State, one-third by the county, and one-third either by the individual himself or some private source. Under the terms of this bill, local health authorities are required to make a survey of their districts and report to the State Department of Health a list of private institutions, boarding houses, or dwellings, in their districts suitable to receive and care for tuberculous persons. The State Department of Health, after investigation, is required to certify a list of such places in different parts of the State as meeting the requirements and to maintain a sys-

tem of inspection after these have begun to operate under the Health Department license. The State and county aid would continue as long as the local authorities deemed it necessary, but in no event more than a year. The plan provides only for patients who are not bedridden. The State Department of Health is authorized to fix uniform rates for board and lodging in licensed places. The bill carries an initial appropriation of $1,000,000.

Foreclosure Sale of Medical Institution.—The New York Medical College and Hospital for Women, which some time ago ceased to exist as a medical college, was sold under foreclosure proceedings on March 29. The Alumnae Association of the institution endeavored to purchase the property, but were overbid by the board of trustees, who acquired the property for $43,500. The institution is continuing to operate as a hospital.

To Increase Nurse Corps.—The number of patients to be cared for in the hospitals of the Public Health Service will be increased from about 50,000 to 75,000 a year under a recent act of Congress designed to meet the growing hospital needs of the enlarged merchant marine. This will necessitate an increase in the nursing force, to meet which the American Red Cross has entered into an agreement with the Public Health Service under which graduate enrolled nurses will be furnished to the service as Red Cross nurses are supplied to the army and navy. There are now only 90 nurses in the United States Public Health Service, but through the cooperation of the Red Cross it is planned to develop the corps in the near future to 750.

A City Hospital Wanted in Washington Heights.—At a recent meeting of the Washington Heights (New York City) Physicians' League plans were perfected for the holding of a monster mass meeting to obtain a city hospital on Washington Heights. It will be held in the auditorium of Public School No. 132, at 182d Street and Wadsworth Avenue, on Wednesday evening, April 9, at 8 P. M. Among the speakers will be Dr. Royal S. Copeland, Commissioner of Health, Mr. Bird S. Coler, Commissioner of Charities, and others.

Medical Society Elections.—The JONES COUNTY (MISS.) MEDICAL SOCIETY, at its recent annual meeting, elected the following officers for the ensuing year: *President*, Dr. R. H. Cranford; *Vice-President*, Dr. C. E. Armstrong; *Secretary-Treasurer*, Dr. J. R. Kittrell.

Obituary Notes.—Dr. LUCIUS THOMAS INGHAM, aged 64, of Lee, Mass., a graduate of Bellevue Hospital Medical College, died March 15, at the "House of Mercy Hospital," in Pittsfield, Mass. He graduated in medicine from the Bellevue Hospital Medical College, New York, in 1886, and then practised for nine months in Germantown, Pa. From there he moved to Amityville, L. I., being resident physician in the Brunswick Home Sanatorium. In March, 1891, he moved to West Stockbridge, Mass., where he resided 13½ years, moving then to Lee. He was a member of the Berkshire Medical Society.

Dr. FRANK READER RIX, of Flushing, L. I., died at the New York Skin and Cancer Hospital, on March 16, aged 65 years. He was a graduate of Harvard Medical School, in 1879, and after practising his profession for fourteen years in Lowell, Mass., he gave it up for a musical career. For eighteen years he has been the Manhattan Borough Supervisor of Musical Education in Public Schools for the New York Board of Education.

Dr. JULIUS F. SIVENY, of Providence, R. I., died from bronchopneumonia at the Peck Memorial Hospital, Brooklyn, on March 16, aged 39 years.

Dr. FREDERICK ROBINSON SMITH, a graduate of the Hahnemann Medical College, Philadelphia, in 1893, died from pneumonia at his home in Rochester, N. Y., on March 25, aged 48 years. He was coroner of Rochester and Imperial Potentate of the Mystic Shrine of North America in 1914.

Dr. JAMES THOMAS MEEHAN, a graduate of New York University Medical College, in 1882, died at his home on March 16, aged 59 years.

Dr. MAX LANDESMAN of New York City died on March 16, aged 57 years. He was a graduate of New York University Medical College in 1893, and visiting physician to the Peoples' Hospital.

Dr. NICHOLAS E. SOULE, a graduate of Harvard Medical School, in 1848, and for many years the oldest living alumnus of Harvard University, died at his home in Exeter, N. H., on March 26, aged 94 years.

Dr. MEVERELL K. ALLEN died of heart disease at his home in Louisville, Ky., on March 15, aged 73 years. He was a graduate of the University of Louisville Medical Department, in 1867, medical director of the Inter-Southern Life Insurance Company, and for fifteen years city health officer of Louisville.

Dr. SAYER HASBROUCK, formerly of Providence, R. I., died, after a lingering illness, at his home in Hamilton, Bermuda, on March 12. He was a member of the American Institute of Homeopathy, the American Homeopathic Ophthalmological, Otological and Laryngological Society, and the New York State Homeopathic Society.

Dr. CHARLES LEO EBNOTHER, a graduate of Charity Hospital Medical College, New Orleans, in 1883, died at his home in Downs, Kan., on March 10, aged 66 years.

Dr. ABNER HUGH COOK died from pneumonia at his home in Hot Springs, Ark., on March 10, aged 33 years. He was commissioned captain after his discharge from the army for work done while he was stationed at Fort Oglethorpe in 1918.

Dr. OSEE WALLACE HOFFMAN of Denver, Col., died of tuberculosis at the Mercy Hospital in that city on March 12, aged 44 years. She was a graduate of the Laura Memorial Woman's Medical College, Cincinanti, Ohio, in 1897.

Dr. BENJAMIN FIDLER, a graduate of Long Island Hospital Medical College, in 1903, died at his home in New York City on March 26, aged 48 years.

Dr. ABEL FITZWATER PRICE, Admiral Dewey's fleet surgeon at the battle of Manila Bay, died in a Springfield, Mass., hospital on March 22, aged 71 years. He was a graduate of the University of Pennsylvania Medical School in 1868, and entered the medical corps of the navy in the same year.

Dr. FRANCIS J. DUFFEY, of Brooklyn, N. Y., died of heart disease while attending a patient on March 31. He was 44 years old and was a graduate of the Long Island College Hospital, in 1896. He was a member of the New York Academy of Medicine and assisting visiting physician to the Post-Graduate Hospital and the Neurological Institute.

Correspondence.

INFLUENZA AND EPILEPSY.

To the Editor of the Medical Record—

Sir:—I note on page 492 of the Medical Record issued March 22, 1919, a reference to an observation made by some French writers, as to the interrelation of influenza and epilepsy.

During October and November, 1918, over eight hundred cases of influenza appeared among the patients at the Craig Colony, all of those affected being epileptics. As had been previously noted, during intercurrent febrile conditions many epileptics continued to have seizures, some an increase, even to the extent of a status epilepticus during the height of the severe influenzal infection. Some patients who had been free from convulsions for some weeks before the influenza manifested a return of symptoms of the epilepsy while ill with influenza, although it could not definitely be established that there was a direct causative relationship. A comparison of the total number of seizures occurring at the Colony during the existence of the epidemic of influenza with the total number of seizures occurring during any period of similar duration before or subsequent to the influenzal period, shows no material difference. Some few patients ordinarily subject to frequent seizures were observed to have no attacks during the influenzal infection, but a study of the records of these particular patients shows that at other times, independent of any other infection, they had similar remissions.

Of the patients developing influenza, the majority showed considerable lung involvement. The death rate was 17.2 per cent. of those having the disease. It was also the experience at the Colony that those patients who were most defective mentally, or physically, or both, developed the most severe type of the disease. But very few of the more intelligent, active patients succumbed to the condition.

William T. Shanahan, M.D.,
Medical Superintendent,
Craig Colony for Epileptics.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, March 6, 1919.

Union National and International.—The perpetual cry in this country is for the union of medical men. A real union of medical men, preferably through existing medical bodies, is very difficult to visualise, but, if it came into existence, its utility would be multiplied and manifolded in many unexpected as well as obvious directions if it were in close alliance with some body formed of enlightened and public spirited laymen who would be able to give to the medical arguments the backing of public policy. This is the plan of union which was projected by the Medical Parliamentary Committee. It is desired to make of that body a kind of informal parliament at which all schools of thought would be represented upon some proportional system. At its table vexed questions could be threshed out, so that information could be given to the legislators based on some sort of consensus of opinion. It would be too much to hope that the opinions of such a body would always be unanimous; and it is possible that, if they were, they would have the appearance of coming from the medical profession with a "take-it-or-leave-it" spirit which would be not acceptable to a legislature composed of reasonable, thinking, and experienced men.

On the other hand, the views of such a body would arrive before Parliament with obvious discrepancies settled, with acrimonious points removed, and with the chances of long debates turning upon unimportant matters very much diminished. For this reason, with measures like those erecting a Ministry of Health or reforming dental practice, awaiting the immediate attention of the House of Commons there is no doubt that such a body would be of great public service.

The public interest in medicine nowadays is manifested in this country in one very obvious way. Medical addresses and lectures, frankly directed to lay audiences, are multiplying in number and attracting much greater attention. Afternoon after afternoon in London addresses for the last year have been delivered before various public bodies in illustration and explanation of such matters as the following: The laws of life, the food supply, the relation of health and sanitation to labor, the right place for nursing in a social scheme, the necessity of safeguarding the younger generation by care of the pregnant woman, care of the nursing mother, care of the infant, including precautions against the rampant causes of infant mortality, and care of the child during education age. At such meetings the policy of the Government, as exemplified in the regulations of the Local Government Board and the Board of Education, and as carried out by the medical staffs of those departments, has received close attention and sometimes valuable criticism. All this means that day by day a larger number of men and women are taking an intelligent interest in the intimate relation of medicine to national life, while that interest is directed along proper channels through the support of accurate information. A public of this improved quality is ripe to take its place in questions of medical reform, and it is a little astonishing to find that many medical men still believe in the contrary policy of trying to decide medical questions without due regard to the public views.

The League of Nations will be sure early to realize that in medicine, and especially in public health and hygiene, bonds between the constituent countries can be found already made and already supported by learning and devotion, whose influence for the creation and welding together of a happier world must be of the tightest nature. It is therefore especially necessary that medicine should internationalize itself as much as possible and that all civilized countries should understand the main objectives of the medical profession in the different nations. Here postgraduate work will be of the greatest value. If the medical men of the various nations will take all the opportunities that can be provided for them to meet each other and learn from each other in an intimate manner their scientific and professional procedures, international medicine will become

the greatest national support of a League of Nations. A start in this way is shortly to be made in London which is of great promise. A scheme has been approved for postgraduate medical education by the London Medical Schools which should place the organization of postgraduate study in London as a center, and later in the country at large, upon a working basis.

The scheme is briefly as follows: It is premised that there are three great classes of practitioners who require postgraduate teaching, namely, general practitioners whose day to day life gives them little opportunity of keeping abreast with new departures, or special development; officers in the army, navy, colonial service, Indian medical service and the air-force service, whose duties may take them for long periods far away from scientific centers; and medical men of the Allied Nations who want to exchange their own national equipment with that of other Allied Nations. The scheme proposes at once to secure the cooperation of America and France. All the London medical schools will arrange to vote to hold classes and demonstrations in different subjects at different dates, covering the whole curriculum between them. The special hospitals will combine with the scheme in London, while it is hoped to bring in all the great provincial, Scottish, and Irish schools. A council is in course of formation, which will elect an executive, etc. Certain sub-committees *ad hoc*, and these latter bodies will be entrusted with the selection and payment of a salaried officiate. The expenses will be met from registration fees and instruction fees of the postgraduate students and the scheme should so far be self-supporting. A big central building is also needed, and the funds for this must emerge from private generosity. Here is where the public has its chance of keeping the medicine of the world at a high level of efficiency.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, February 22, 1919.

Returning to Pre-war Conditions.—All those who have visited Paris will remember the Grand Palais and Petit Palais on the Avenue des Champs Elysées, where annually was held the Salon of Painting and Sculpture. The larger of these two magnificent buildings was requisitioned by the French Government and turned into a hospital with 1,500 beds, with surgical and medical services, auxiliary services of various kinds, reeducation for the crippled, physiotherapy, mechanotherapy, gymnasium, convalescent center, depot for soldiers without homes, and finally a department under the excellent direction of Mrs. Nicolas C. Eliasco devoted to the reeducation of French and American cripples.

The Department of Beaux Arts has requested the government to vacate and return to their use the great hall and gallery on the first floor and permit them to organize an exhibition for June next and this necessitates the removal of some of the departments of service to less commodious quarters in the building. This action is the cause of some public criticism, but is a healthy sign of the high morale of the public mind which desires to resume its ordinary peaceful occupations even before the actual outcome of the Peace Conference is known.

Demobilization of the Ambulance Corps.—Headquarters' plans for the early demobilization of the U. S. Army Ambulance Service with the French Army point to the probability that by the end of July every man in the corps will return to the joys of civilian life. There are about eighty-one sections serving in the French armies at the front. According to the present plan, ten sections will be sent home during the month of February and twenty sections each month thereafter, until the entire service has embarked for the United States. Which sections are going first? The evident answer to that question is that the sections which have been longest in France will be the first to leave. This is the plan that will be adhered to as far as practicable. The same rule will apply to individuals.

If Private Jones, who has served four months in France, is now with a section that has been in France more than a year, he will be transferred out—that is, if the transfer is compatible with the interests of the service—and Private Smith, now a casual or on detached service, who has been in France more than a year, will be shifted to the section in order to take his proper turn in going home. Just because one had hard luck and had to leave his section and become a casual will make no difference in his chances of going home in his turn. In fact, there will be no luck to it. It will simply be a determination of his turn from the length of time he has served with the United States Army in France. All he has to do is count his service stripes. If he has two and the other fellow has only one, he knows he will beat him home. If, on account of impaired health, one deserves to go out of his turn, that fact will be known from the medical files of the attending surgeon. All he has to do is to sit tight and wait till his turn comes.

The necessary arrangements have been effected whereby the released sections can be concentrated at the base camp, where all records can be completed, and from there the sections will go to the port of embarkation. The Ambulance Service is one of the oldest A. E. F., organizations in France, and for that reason it is thought it will be given perference in sailing orders.

Increasing Death Rate.—According to the figures published by the Paris statistical service for the sixth week of the year it would appear that the death rate was somewhat on the increase with a total of 1,213 deaths, as compared with 1,076, the average for the season. Spanish "flu" is credited with ninety-one victims. There were seventy-five deaths due to violence, and six to suicide.

146, AVENUE DES CHAMPS ELYSÉES.

Medical Streptococcus Septicæmia.—Rathery and du Castel in connection with the known rarity of this affection in war medicine relate a case remarkable for a papulo-hemorrhagic and phlyctenular eruption, generalized contractures and special type of massive bronchopneumonia, purulent and of rapid evolution.—*La Presse Médicale.*

2. The Value and Limitations of Radium in the Treatment of Cancer.—Russell H. Boggs points out that the value of radium therapy in malignant growths has been established and is incontestible; that it varies according to the region and nature of the lesion and its condition at the time radium treatment is instituted; and that, while we must not lose sight of other methods, since in many cases the best results are obtained by a judicious combination of the different therapeutic agencies, radium holds its own as a curative measure and as a palliative procedure. Treatment of hopeless carcinoma in the past has been with morphine; today it should be radiotherapy. The leading surgical authorities today are beginning to recognize radium as a legitimate method of treatment. It is pitiful that patients with inoperable carcinoma, after their condition is pronounced hopeless, receive so little consideration. One of the most striking results of radium therapy is that the secretions which are often offensive disappear almost in every case. Thorough knowledge of the action of radium is essential because from that knowledge only may the proper dose be applied to produce the best results. Haphazard use of radium is today discouraged. In estimating the value of radium therapy, its advocates do not claim that it supersedes surgery, but that it is a valuable adjunct to surgery, in helping to prevent recurrences after operation and in rendering inoperable cases operable, and that it has proved itself one of the best palliatives we have in cases in which operation is impracticable and in many of such cases has brought about an apparent cure. Radium should always be considered first in the treatment of epithelioma, because when properly applied, practically epitheliomatous tissue can be made to disappear and there are fewer recurrences than by any other method. Formerly radiotherapy was advised on account of its leaving practically no scar; today the principal reason for treating these cases with radium is that the end results are superior to any other method. It is a demonstrated fact that radium has the power of inhibiting the proliferation of the cancer cell. In this way it has been shown that malignant growths are retarded by radium and become less malignant although they have not been reduced in size or have disappeared. By more intense radiation the cancer cells are completely destroyed. When this has been accomplished without seriously injuring the surrounding healthy tissue, it comes nearer to a cure for carcinoma than surgery or any method which has been employed up to the present time. This can be accomplished in at least 90 per cent. of all epitheliomata and this is the reason it is the best routine treatment. In the treatment of advanced epithelioma of the mouth and throat, by giving intense radiation to a point where some of the surrounding healthy tissue is destroyed, more of the malignant cells can be destroyed by radium and more cures can be produced than by any other method. When radium is pushed to this point, it is necessary in many cases to remove some of the healthy tissues which have undergone necrosis or degeneration by fulguration or surgery. Radium in tubes arranged at a certain distance apart and at a certain distance from the skin, placed over the submental and submaxillary (which are junctions of the lymphatics) so these areas are bombed with intensive radiation, and the adjacent lymphatics treated by deep röntgenotherapy, is more effective in destroying the malignant cells in the lymphatics of the neck than the most careful dissection of the neck. Glands have been removed and examined under the microscope in a sufficient number of cases after such radiation to verify this statement. In recurrent and inoperable carcinoma of the uterus, radium might be considered the specific treatment, because it is the only method which retards the process to the same extent and gives the same amount of palliation. Radium is always more valuable in inoperable than recurrent carcinoma of the uterus, because about one-fourth to one-third of these cases are clinically cured for a time. Since so much has been accomplished in the inoperable cases of carcinoma, in every primary case, no matter how early the operation has been performed, there should be either anteoperative or postoperative radium treatment, or both.

4. Abdominal Complications of the Influenza Epidemic at Camp Custer, Mich.—Lynn S. Beals, Wyndham B. Blanton, and Daniel N. Eisendrath found that the variation in the clinical pictures of the abdominal complications in the influenza epidemic was so great that they have grouped the cases into nine series. (1) Abdominal rigidity and tenderness. In these cases the question arose as to whether the boardlike rigidity of one or both upper quadrants of the abdomen was due to acute abdominal affection or to muscle spasm from lesions of the chest. The authors believe that the upper abdominal pain, which has always been held to be reflex, has an actual pathologic basis in at least some of the cases. (2) Pain in the right lower quadrant. In these cases pain was usually of a dull, aching character. On examination there was only slight rigidity in a small number, and in the majority there was tenderness over the region of the appendix but not rigidity. These signs frequently disappeared in a short time. In some cases, however, they persisted and increased in severity so that operation was deemed imperative. In this group nearly all the patients later showed demonstrable signs of bronchopneumonia, but a small number of fulminant cases of appendicitis occurred, in which operation was performed under local anesthesia with good results. (3) Peritonitis. Acute peritonitis occurred in 4.2 per cent. of the authors' cases of bronchopneumonia following influenza. The fact that in two out of these six cases the process was localized to the upper quadrant, and in a third, though distributed throughout the peritoneum, was most advanced over the hepatic surface, suggests an origin by direct extension through the diaphragm. In each of these cases a hemolyzing streptococcus was recovered. In two instances, pericarditis was an accompanying finding, and in one, jaundice was present. In addition to a bronchopneumonia, which in most cases was resolving, pleurisy was present. It seems certain therefore that the peritoneal infection was hematogenous in origin and did not in all cases originate by

the transdiaphragmatic route. In no case was the appendix or gall bladder the site of any change except on the serous coat. In five out of the six cases a diagnosis of peritonitis was not made during life. The condition was not secondary to any demonstrable abdominal focus, but apparently was one manifestation of generalized infection, which frequently was evident in pleura and pericardium. Suppurative peritonitis was not found in necropsies in the early fulminating cases, but only later in the epidemic. The early occurrence of deaths did not afford time for the development of the condition. A similar group of cases was noted during the severe infections in the early part of 1918. (4) Subphrenic abscess. Two cases occurred during the latter portion of the epidemic, and in this connection the authors point out the necessity of thorough routine examinations. (5) Jaundice was present in 7 per cent. of 140 necropsies. In all except one, a bacteriemia was demonstrable; *Streptococcus hemolyticus* was present in three; *Streptococcus viridans* in three; and the pneumococcus type IV in two cases. In only one case was there swelling of the ampulla of Vater. In all cases the intestinal contents showed that bile was freely passing into the intestine, and stools examined during life gave no evidence of obstruction of the flow of bile. (6) Spleen. In the majority of cases the spleen was but little enlarged; it was moderately firm on section and red. Microscopically the predominating feature was marked congestion. (7) Kidney. Acute nephritis was extremely rare. Acute congestion of the kidneys, however, was frequent. In one case multiple abscesses of the kidney were a part of a hemolytic streptococcal septicemia which had also caused a severe infection of one of the toes. Pyelitis demonstrated by ureteral catheterization was occasionally found. The authors point out that both renal and perirenal localization may be so severe as to endanger life, either concurrently with a pulmonary condition or independently of any demonstrated focus. (8) Rupture of the rectus muscles. This occurred with such frequency as to attract special notice. The condition was seen in eight cases at necropsy, rupture occurring midway between the symphysis pubis and the umbilicus. It was never complete and always bilateral. It was accompanied by hemorrhage under the sheath of the muscles. In one case the hemorrhage was extensive, dissecting its way downward in front of the bladder; in another, a broken-down hematoma under the muscle sheath showed hemolytic streptococci. In cases studied microscopically the same condition was seen, namely, polymorphonuclear leucocytes and mononuclear wandering cells accumulated diffusely between the muscle fibers and here and there localized into definite abscesses. The presence of well preserved erythrocytes in the tissues points to the fact that rupture was usually a late occurrence in the disease, and the authors believe that the probable explanation is that a localization of the infection in the muscles with abscess formation so weakens the muscle that rupture occurs with violent coughing or terminal muscle spasms. (9) Thrombophlebitis. This occurred four times, or 2.7 per cent. In three cases it led to pulmonary embolism. In one instance the thrombus had its origin at the bifurcation of the inferior vena cava, extended into the iliacs of both sides, and could be traced in the femorals to the middle of both thighs; this patient had marked swelling of both legs to the iliac crests. In another instance the right internal iliac vein was the seat of the thrombus, and in a third case old infarcts and plugged pulmonary vessels originated in a partly healed phlebitis. Blood cultures were negative. This affection is also one of the late manifestations of the epidemic and occurred in patients who had been sick for a month or more.

4. Wheelhouse's Operation: Some Points Which Assist in Its Performance. James B. Macalpine.
5. Gunshot Injuries of the Cervical Nerve Roots. John S. B. Stopford.

3. Chronic Intestinal Stasis: What Are the Indications for Operative Interference?—Sir W. Arbuthnot Lane points out that in the vast proportion of cases of intestinal stasis operation is unnecessary since the administration of paraffin before meals, the use of a Curtis belt, the assumption of the recumbent posture at intervals, careful dieting, and the employment of drugs to relieve hyperacidity, will usually afford complete relief. Operative interference, however, is indicated in cases in which gastroduodenal distension is due to a damming back of the ileal contents by the pressure exerted by a "controlling appendix" or by an "ileal kink." The degree of interference can be determined by the appearance of the patient, the history of the case, the pain elicited on pressure on the inflamed and hypertrophied end of the ileum, and the *x*-ray findings. The utility of a complete report on the passage of a bismuth meal by a competent and experienced radiographer cannot be exaggerated, but unless he is familiar with existing mechanical conditions the services of a radiographer are of little value to the surgeon. The removal of the anchored appendix or the freeing of the ileal kink is usually sufficient to liberate the duodeno-jejunal junction from the strain. It is well to remember that the membrane which produces the ileal kink when well developed appears to contain lymphatics which drain the most infected portion of the ileum. Therefore, after the acquired band has been carefully separated from the mesentery and the torn peritoneal edges placed in accurate apposition, a drainage tube should be left in for two or three days, a precaution which may save the patient's life. It must be remembered that the kink tends to reform if the factors which produce it remain in action. Should the symptoms of the *x*-ray report suggest obstruction elsewhere, especially at the "last kink," it should be operated on at the same time. Gastroenterostomy should be performed when a peptic ulcer is present in the stomach or duodenum, or both. If it seems advisable, a gastric ulcer should be excised or it should be otherwise dealt with to ensure its cure. When the stomach and duodenum are dilated and the latter obstructed by such a degree of kinking at the duodenal jejunal junction that no freeing of the stasis in the lower bowel is likely to be sufficient to overcome this angulation, and as these constitute antecedent changes in a sequence which ends in peptic ulceration and, finally, in cancer, a gastroenterostomy should be performed. In peptic ulcer it is not sufficient to limit the operation to establishing a communication between the stomach and jejunum. The end of the ileum should be carefully examined and any obstruction removed, and the "last kink" should be dealt with if it is exerting any abnormal control, as is usually the case in these conditions. The surgeon is too prone to do his work through a small opening, and this is largely responsible for his frequent failures to understand the conditions he is dealing with and to benefit his patient. A more extensive incision than is usually made is necessary. By carefully observing the form and functioning of the stomach and duodenum, and by gauging the effect of traction on the duodenojejunal junction, the surgeon should be able to decide between a gastroenterostomy and treatment of conditions controlling the intestine lower in the tract. The operation called gastroduodenostomy, in which in cases of pyloric obstruction, a communication is established between the stomach and the distended duodenum, shows how little the mechanical causation of peptic ulcers is understood; as it is distended, the duodenum must necessarily be obstructed at the duodenojejunal junction. In cholecystitis, with or without gallstones, the primary cause of infection in the intestinal canal must be carefully investigated. Colectomy is indicated in such conditions as extreme constipation in which an evacuation can be obtained only at intervals and with great difficulty and pain; rapid and progressive wasting; mental depression which may result in attempted suicide; total inability to lead an active life; distressing absence of sexual desire; progressive degenerative changes in the

breasts of those with marked family history of cancer; toxic changes in the heart and circulation, and all secondary conditions such as rheumatoid arthritis, Raynaud's disease, Still's disease, many forms of tubercle, Bright's disease, Addison's disease. In these and many other conditions, colectomy offers the only hope of cure. Lane points out that by colectomy, he means the *complete* removal of the large bowel with exception of a sufficient length of the pelvic colon to establish continuity. He is of opinion that removal of the cecum, ascending and part of the transverse colon, rarely serves a useful purpose. Should no complication, such as the development of adhesions, supervene, the health of the patient improves marvelously after colectomy. The delay in the small intestine as shown by *x*-rays affords a general indication as to the extent of surgical interference necessary, but the degree of autointoxication and the delay do not necessarily correspond, for the reason that a moderate amount of stasis may be associated with a very virulent infection, or vice-versa. The surgeon must be guided largely by the severity of the symptoms, and his experience and instinct. A very long pelvic colon associated with much sepsis calls for colectomy, while a large, prolapsed, and twisted cecum can practically be dealt with in no other way. The surgeon will rarely regret having performed a colectomy, though he may frequently wish he had done this instead of some lesser operation. The vast majority of colectomies are performed for autointoxication and its results and not for mechanical effects of stasis. In many cases of colitis the only effectual treatment is the removal of the large intestine; it should be remembered that in ulcerative colitis, the process may extend for a distance up the ileum, and that the ulcerated segment of the small intestine should be removed. The pelvic colon is also ulcerated in many cases. This necessitates the subsequent treatment of the residual ulceration by vaccines, etc. In cancer of the large bowel, it is safer and easier to remove the whole of the bowel above the pelvic brim than a portion of it, and the health of the patient is benefited to a much greater extent by the more extensive operation.

4. The Treatment of Influenza.—Captains William D. D. Small and W. O. Blanchard describe the method of treatment followed in a series of 937 cases admitted to a general hospital in France, in which the mortality was 26 or 27 per cent. As these figures compare very favorably with the results obtained elsewhere, particularly as many of the cases were of a most virulent type, the authors have thought well to outlne their mode of procedure. The general management was that of fever. The patients were given lots of fresh air, were kept warm with blankets and hot water bottles but were not overheated, and were permitted a light diet consisting of fluids, milk, beef-tea, which was especially valuable, clear soups, egg-nogs, jellies, and custards. In order to reduce the toxemia, the drinking of large quantities of water, barley water, or lemon water is encouraged. These authors emphasize the necessity of absolute rest during the acute stage. Examinations should be as brief as possible and the patient should be disturbed as little as possible, however desirable it may be from an academic point of view to determine the precise nature and extent of the pulmonary complications. Sleep must be ensured, especially in patients showing pronounced tremor. It is the custom of the authors never to allow a sleepless night; it always reflects on the general condition and may make the difference between recovery and death. If tepid sponging is insufficient to promote sleep, one-twelfth grain of heroin should be given hypodermically and repeated once or twice, if necessary, at intervals of an hour and a half, until sleep is obtained. As to medicinal treatment, the authors have tested various drugs. Groups of patients—fifteen in each—were put upon each of the following drugs and progress noted and compared: aconite, aspirin, sodium salicylate, belladonna, arsenic, quinine, Dover's powder, and gelsemium. Gelsemium was found to be by far the most effective of these drugs and the contrast was so great that it was possible to pick out the cases treated with it without knowing that they had been so treated. It exerted a marked beneficial action on the course of the disease, it shortened the illness, and rapidly relieved the discomfort of the patient. Beyond slight ocular disturbances in a very small number of cases, no disadvantages were observed from its use. Belladonna was also found to be of benefit and the authors therefore advise its use in combination with gelsemium. In severe toxic cases with marked pulmonary symptoms, where tremor is marked, the pulse unstable, and the patient collapsed, stimulants are indicated. Alcohol in the form of brandy, whisky, or champagne gives the best results, the usual dose required being half an ounce every four hours, or more if necessary. Should there be any suggestion of overdosage, aromatic spirits of ammonium (½ to 1 dram) may be substituted. When there are signs of cardiac failure tincture of digitalis is of value. Caffeine, strychnine, and adrenalin produced no beneficial action of any kind. The treatment of pulmonary complications was carried on along the usual lines. The authors note, however, that the compound tincture of chloroform and morphine (10 minims every four hours) was particularly efficient in soothing the cough, and that inhalations of menthol and benzoin greatly relieved the tightness in the chest. The type of influenza seen during the recent epidemic produces extreme debility frequently associated with circulatory symptoms. During convalescence, therefore, a period of comparative rest is indicated with nourishing diet and tonics.

6. Treatment of Wounds by Paraffin.—Captain E. F. Pratt reports excellent results from the treatment of lacerated wounds and burns by ambrine and No. 7 paraffin, which mediums he has found equally satisfactory. His method of procedure is as follows: The wound or burn is first thoroughly cleansed with sterilized water; the paraffin is then melted and either sprayed by a special spray or painted by a sterilized brush over the affected area. One layer of gauze is then placed over the injured part, and then another layer of melted paraffin is either sprayed or painted over the gauze. On top of this a cotton wool pad is placed and the part bandaged. The dressing is left undisturbed for twenty-four hours, when it is removed and a fresh application made. A third dressing is applied in ordinary cases the next day and, when necessary, a fourth dressing after that. This method has been used in more than thirty cases and there has been no failure to relieve pain immediately, to prevent or remove sepsis, and to produce healing, in at most five dressings. Without exception, all the cases treated in this way healed up in a week. Captain Pratt believes that in maior injuries equally good results should be obtained. He suggests that since paraffin is the most important of the three ingredients in "bipp," that the efficiency of this medium may be due to the paraffin. Should this prove to be so, the principal objections to the use of bipp, namely, the expense, the risk of toxic symptoms, and the possibility of some interference with *x*-ray examinations, would be reduced to a minimum. He is of opinion that the view that antiseptic paraffin retards the process of healing by destroying the saprophytic action of bacteria is unsound and without foundation.

1. So-called Heart Block: Report of a Case, Including a Brief Review of Recent Literature.—Henry E. Pelle is of the opinion that from a scientific or at least a technical standpoint, heart block seems totally inexpressive, inappropriate, and a misnomer, since the cardia itself does not become blocked. As at present used heart block may be defined as a circulatory phenomenon or symptom-complex in which the stimulus for contraction transmitted from auricle to ventricle by muscular fibers, bundle of His, is stopped or blocked. Defective conduction or transmission may be due to known or unknown underlying pathology. Lesions involving the auriculoventricular bundle must be exceedingly rare. A multitude of presumed exciting or contributing causative factors have been mentioned by those indulging in theoretical speculation, but so far as can be ascertained no definite or constant etiological factor has yet been established. Anatomically heart block has been classified according to the location of the inefficiency, thus: (*a*) auriculoventricular, when located at the auriculoventricular junction. (*b*) sino-auricular when at the sino-auricular junction. (*c*) dextroauriculo-septolevauricular, when at the line of union of the right auricle plus the interauricular septum. (*d*) Septodextroauriculo-levauricular, when at the line of union of the right auricle plus the interauricular septum with the left auricle. According to Blackford and Willius, complete, chronic heart block owes its origin to a functionally complete "break" in the auriculoventricular bundle, *i.e.* failure of conduction from organic severance. Pathologically, inflammation, degeneration, infitrating gummata, and neoplasms are the chief lesions described. Valvular defects and coronary sclerosis are usually present. The most frequent valvular lesion is the initial. Progressive changes in cardiac rhythm from definite prolongation of the auriculoventricular interval to the "dropped" beat, then to 2-1 and 3-1 rhythm and finally to complete dissociation of rhythm, have been recognized and described. The Stokes-Adams syndrome results from circulatory changes which produce cerebral anemia; in certain instances exercise seems to be the responsible factor, since there is no compensatory increase in the ventricular rate. Rare instances have been recorded where complete block existed for many years with little or no clinical discomfort and in which no organic lesion was evident. However, the majority of patients with chronic heart block are confirmed cardiopaths, subject to the Stokes-Adams syndrome with its attendant dangers. Pelle quotes a case of his own and several cases by other observers in which heart block was present with somewhat varying symptoms in the different cases. As for treatment Blackford and Willius are quoted as concluding: 1. Alphaiodin quickens the iodioventricular rate in complete heart block; this is followed by marked subjective relief to the patient; the drug must be pushed to tolerance and the dose then reduced to the largest quantity which may be taken without discomfort; the auricular rate increases much earlier and to a much higher figure proportionately than the ventricular rate. 2. In nine cases of complete heart block, eight patients gave evidence of definite valvular disease, initial lesions predominating; the ninth patient had advanced nephritis. 3. In none of the nine cases was there a probable venereal etiology. 4. Six patients gave a history of probable etiologic infection with the streptococcic group, *i.e.* chronic arthritis, one case, "grip" and tonsillitis, five cases; diphtheria seems to have been responsible in two instances; the ninth patient gave no history of previous infection, but at the autopsy a large mulberry calcified nodule was found involving the bundle and one cusp of the aortic valve; no other pathology was evident. 5. Digitalis should be used in all cases of chronic heart block in which there is evidence of myocardial insufficiency. 6. They do not know the effects of long continued administration of large doses of alphaiodin in patients not suffering from thyroid insufficiency; therefore they believe that for the present this medication should be used only to relieve the Stokes-Adams syndrome in chronic heart block.

2. Asthma of Nasal Origin. John E. Barnhill.
3. Personal Incidents During Service in France. William F Clevenger.
4. Clinical Report of Alcoholic Cirrhosis with Cardiac Disturbance. S. E. Earp.

2. Asthma of Nasal Origin.—John F. Barnhill points out that asthma of nasal origin is quite common and that moreover its origin in the upper air tract is not always recognized. Every case of asthma should be looked upon as of possible nasal origin and therefore every effort should be made to discover whether or not its seat is nasal or nasopharyngeal. Of the nasal inflammatory infections Barnhill regards ethmoiditis as the most frequent cause of asthma. The name does not have the same familiar ring as tonsillitis, peritonitis, or appendicitis, yet the disease is as common as any of these and gives rise to much suffering, both local and general. Undoubtedly asthma is among the latter. Nasal infections undoubtedly lead in many instances to congestion and infiltration of the tracheal lining and to hypersensitive bronchial mucosa, conditions especially conducive to the asthmatic state. The second cause is a nervous one. This is, of course, apparent from the clinical fact that many instances may be cited of patients who have ethmoiditis or other nasal disease entirely sufficient to cause asthma, together with bronchial inflammation, who never have attacks of asthma. Neurotic influence must also be taken into account to explain the fact that most all attacks of asthma are paroxysmal in character. The treatment of asthma of nasal origin is successful in perhaps a majority of cases. As in many other diseases, success depends upon reasonably early diagnosis and surgical treatment. When untreated until serious changes in the bronchioles have occurred all treatment may prove unsatisfactory. Surgery directed toward the removal of nasal obstruction including the hypersensitive nerve terminals which supply such areas, supplemented by therapeutics and followed sometimes by sojourns in a suitable climate, have cured a large percentage of cases. Often the cure of a case is a purely surgical problem, but one that is far from simple. Not infrequently the nose must be completely renovated and changed. In some cases one must deal surgically with a much deformed nasal septum, hypertrophied turbinates, and ethmoidal inflammation or perhaps with ethmoidal degeneration with polypi. When the nasal disease is so extensive one or more nasal accessory sinuses are empyemic. In all such cases the patient has constant cold, with great distress from nasal stoppage and sneezing. Nasal infections are frequent and these spread quickly to the larynx, trachea, and bronchi, with asthmatic attacks. In this type of case nasal sprays, especially those with watery base, do harm. Internal medicines and climate are but palliative, but well directed and thoroughly executed nasal surgery is imperative and curative. All necessary surgery may not be done at one operation. Sometimes several operations may be necessary. The surgical aim is to break up the over-sensitive nerve relationship between the nose and bronchial tree, and to prevent in so far as is possible any further infection of the lower air spaces through the presence of infection in the numerous foci of the nose and throat. These operations are often major. They should be performed in a hospital.

Berliner klinische Wochenschrift.

January 27, 1919.

Under the general heading of "The State, Physicians and the People," appear a series of articles the object

of which is to show the German nation and Socialist government now in power, the useful part played by the medical corps in "bourgeoise" society. These articles, which possess a greater political and sociological interest than a medical one, are intended to fortify the position of the medical profession in the struggle for power.

The Object and Service Rendered by the Board of Public Health and the Sanitary Board.—By Kirchner.

The Development of the Sanitary Board and Board of Social Hygiene Up to the November Revolution.—By E. Deitrich.

Scientific Medical Research and the People.—A. von Wassermann demonstrates the necessity for a scientific medical corps for research work. If there is a body which denies itself honors and material advantages, it is certainly this one. The writer recalls in this respect that the legislation interdicts the patenting of diagnostic and therapeutic discoveries. The writer, who has had an experience of twenty-five years, during which he has seen men of science at close range, such as Koch and Ehrlich, declares that for them the attraction of a discovery is far greater than that of pecuniary results. The disinterestedness of scientific medical workers is for that matter an universally recognized fact. Wassermann pays an exalted tribute to the Pasteur Institute of Paris and to the laboratories of the United States, and apparently is getting ready for a *peaceful invasion* of the soil of scientific medical men of the Entente after peace is signed. He then recalls the fact that scientific research is a powerful stimulant for the social machine, viz., chemical manufactures and those of electric and radiological instrumentation.

Münchener medizinische Wochenschrift.

January 24, 1919.

Studies on a Toxin of Gas Edema and Its Antitoxin.—W. Straub has experimented with a sterile filtrate derived from cultures of gas edema bacillus and obtained by Fricker's procedure. The toxicity of the filtrate is considerable. In the first place a cardiac action, similar to that produced by digitalis, is noted, consisting of a ventricular paralysis with a maximum increase of the tonus, followed by paralysis of the respiration. The toxicity is markedly influenced by the rapidity with which the injection is given, while an intraarterial injection is less marked in effect than an intravenous one, because of the fact that the filtrate passing through the capillaries already diminishes the toxicity of the toxin, it being rapidly oxygenated by the tissues. These data may throw some light on the symptomatology of gas edema as met with clinically in man. Experiments were likewise carried out with an antitoxin and it was possible to demonstrate that it neutralized an amount of toxin one hundred times greater. The period of sensibilization for the toxin resulting from the injection of the antitoxin lasts for several days. Its action is above all preventive, the curative action being rendered more difficult from the rapidity of the action of the toxin of gas edema.

Cerebral Edema from Salvarsan.—A. Stühmer reports several cases of acute accidents following the injection of salvarsan. These consisted of cerebral edema even reaching punctiform hemorrhages. These accidents, which are due to anaphylaxis, occur most frequently when the injections are given too far apart. It is better to give the injections within less than ten days of each other in order to avoid this complication. If it occurs, it should be treated by intravenous or intralumbar injections of normal serum, while free trepanation is the best means of dealing with the cerebral compression resulting from the edema.

Deutsche medizinische Wochenschrift.

January 23, 1919

New Essays and Observations on Simulation.—R. H. Hübner records some experiments that he carried out in order to ascertain to what extent psychic affections can be simulated. To attain this end the writer requests the subject (in the special instance the subject was a neurotic female, having a taste for the stage and having a sister who is a cinema actress) to observe various types of insane subjects and afterwards to reproduce as exactly as possible a given psychosis. Hübner's subject could finally so exactly simulate melancholia that he sent her to a confrère specialist who did not hesitate to take the necessary steps to place her in an asylum! Mania was more difficult to simulate, the subject in question having great difficulty to assimilate the symptom of the "flight of ideas." She was also able to simulate general paralysis, but the speech characteristic of this affection required a rather long apprenticeship. The writer refers to the interest that these experiments may have in the domain of simulation and in the differential diagnosis of hysteria and other psychoses.

Wiener medizinische Wochenschrift.

January 11, 1919.

Non-Traumatic Organic Nervous Diseases in Soldiers.—J. P. Karplus sums up, in an article without pretension to novelty, the various affections which should be regarded as belonging to warfare. He refers more particularly to the neuritides and polyneuritides (there is no polyneuritis of warfare due to factors such as "nerve fag" or neurasthenia), to sclerosis "en plaques" (two cases following shell shock), to myelitides, encephalitis, syringomyelia, various syphilitic affections (it would appear that the fatigues of war do not predispose to, or accelerate the development of tabes in luetics) to tuberculous spondylitis, neoplasms, lateral amytrophic scleroses, Thomsen's disease, etc.

Le Progrès Médical.

February 22, 1919.

Nature of Cancer.—Audrain plunges at once into the resemblance between the syncytium of the placenta and cancer. This is admitted everywhere, but which is the natural type and which the analogue? Is cancer a something which the syncytium closely resembles, or is the syncytium the norm and cancer the simulator? Bard in 1899 called attention to the anarchy of the cancer cells. Does the syncytium possess the same attribute? No. The latter is physiological and orderly when it penetrates the uterine mucosa. It does not destroy right and left but only for a definite purpose and in a circumscribed manner. Its cells are disciplined while cancer cells are without discipline. We do not know what is the source of the syncytium, for while composed of embryonal cells it does not assist in the formation of the embryo. Cancer cells represent a cellular revolt which ends in the death of both the cells themselves and the tissues in which they proliferate. Slight irritation maintained or a sudden shock is sufficient to cause this revolt only in predisposed tissues. The author here interjects the remark that the syphilis toxin causes phenomena of functional exaltation, as bulimia, excessive fecundity, exaggeration of personality, etc. It might conceivably contribute in the revolt of cancer cell as a predisposing cause. This is purely speculation and not necessarily supported by facts. Syphilis is known to persist to the fourth generation. While the connection between syphilis and cancer in the same individual is not marked it may be otherwise in strains of blood, for syphilis in remote ancestors might result in cancer in the descendants.

Correspondenz-Blatt für Schweizer Aerzte.

February 1, 1919.

Lumbago.—Pometta, who is at the head of the medical department of the Swiss Accident Insurance Institute, refers to the consensus of medical opinion that this affection is mostly of rheumatic origin and that even the traumatically conditioned form is not usually traumatic in the insurance sense. In many cases the trouble follows certain definite movements, but this does not make the cases traumatic. The author has always refused to commit himself to arbitrary generalizations, for every case requires individual study. In every case he goes through a routine. Was the subject making a habitual movement in a habitual way when the lumbago

was elicited. Was he in an unusual posture when the movement was made? Was the movement exerted in a brusque manner? Was the effort made without premeditation? In this way an accident in the insurance sense may sometimes be shown. But as a rule the effort which elicits the lumbago is a minimal one. Moreover in a true accident there should be evidence that the affected muscle has sustained some pathological process. The muscle may have sustained rupture of a few fibers or may simply have been strained; but an actual demonstration of such injury is most difficult. If such can be assumed, it is evident that a reparative process must take place and that a certain time must first elapse. The presence or absence of pain cuts no figure, for the test of recovery is renewed ability to work at one's occupation and a relapse need not be feared. The best treatment of lumbago, however, is not rest but massage. In known cases of muscular traumatism aside from lumbago we know that improvement is very rapid provided necrosis or suppuration does not occur. In a few days the condition becomes quite painless. In the Simplon Tunnel it was common for men to be hit on the back by fragments of stone while stooped over. The resulting injury would not be termed lumbago, but it gives a line as to the time required for actual muscle lesions to heal. By the second or third day in uncomplicated cases pain had subsided. Hence in the much less and usually undemonstrable lesions of lumbago any damage must be quickly repaired. In practice it is well, to be on the safe side, to allow a week and to tell the patient that he will be well in from 6 to 8 days at the outside. One should never make this interval 2 or 3 weeks for the patient would probably make it come true. It must be borne in mind that this rapid healing holds good for the purely traumatic case, but lumbago, irrespective of nature, is said to last about one week. In the traumatic case a longer interval would suggest some special kind of injury and in general delayed recovery could be set down to muscular rheumatism, for in some rheumatic individals lightning twinges may visit the lumbar muscles if the weather is favorable. A purely rheumatic case should not be difficult of recognition. Outside of accident practice rheumatic lumbago is the form commonly seen, but in general the profession are apt when they encounter lumbago to look for rheumatism and imagine its presence where it does not exist. But there is a fallacy here. A man who is free from rheumatism and without history pointing to the same may when overheated and then cooled suddenly by a draft develop any of the so-called rheumatic affections as wryneck, or refrigeration palsy of the facialis. Such lumbago is not of course traumatic, nor is it rheumatic in the strict sense, but in examination the question of exposure to drafts while heated must be agitated. When exposure of any kind in an untainted individual can be shown there is nothing to do but class it under rheumatic affections. The traumatic history in a given case may be shown to be accompanied by a history of exposure. In accident practice failure to recover in 8 days becomes of great significance, for we have to exclude malingering for revenue, and determine the reasons for delayed recovery. Experts have advised such victims to return to work and work it off, for continued inactivity would be harmful. The author now proceeds to discuss severe injuries of the loin muscles in which there are swelling and hematoma and perhaps injuries to the spine.

Nederlansch Tijdschrift voor Geneeskunde.

December 14, 1918.

Grippe in Holland.—Since the second or severe grippe wave visited this country the above periodical has contained little else than accounts of cases and generalities about the epidemic. The present number is no exception and contains six articles which deal respectively with diagnosis, grippe and pregnancy, grippe and purpura and the sublimate treatment of grippe, the latter subject claiming three articles. Under diagnosis Nicolai mentions a case with an exanthem and other atypical behavior, such as enteritis. The author made a diagnosis of influenza upon which he later cast doubts. The case ended fatally without mention of autopsy. Dyspnea was marked and evidently of the type known as *dyspnea sine materia*, first mentioned by Graves in 1830 as seen in the influenza epidemic of that year. The various phenomena of conjunctivitis, general wheal-like eruption, enteritis, dyspnea, etc., could be explained in part by an angioneurotic process, but the high fever, delirium, and cardiac failure pointed to scarlet fever. In another case the diagnosis between influenza and typhoid was very difficult. Engelkens mentions the cases of 16 pregnant women with an infantile mortality of 50 per cent. as a result of influenza. Apparently there was no maternal mortality in this series. Niemeijer relates a case of influenza which appears to cause acute hemorrhagic diathesis. A number of cases are related in which sublimate injections appeared to act favorably in severe cases of grippe.

Revue médicale de la Suisse romande.

January 20, 1919.

Observations on the Influenza.—Galli-Valerio mentions the extreme confusion which prevailed on this subject on the part of all men directly concerned in its prevention and treatment. The first cases seen by the writer in early July gave the impression of the grippe of 1889 due to Pfeiffer's bacillus with secondary pneumococcus complications. This was soon followed by strange hypotheses that something different was afloat —why should the pandemic have begun in Spain instead of in Russian Asia? Why was Pfeiffer's bacillus so little in evidence? As for a Spanish origin it has long ago been shown that masked influenza was present at the same time in other countries. As for Pfeiffer's bacillus it certainly comes more and more into evidence as the pandemic advances and recedes and the author shows at great length that with technical refinement and perseverance its presence may often be indicated after preliminary reports of a negative character. Statements of unusual vulnerability with tendency to escape observation on this account cannot be endorsed for the germ seems quite hardy, surviving undesiccation and other unfavorable influences. Next to be considered is the subject of acquired immunity. We know that influenza in the present pandemic can relapse or that reinfection is possible, but as a rule the second attack is milder than the first. In second attacks with a considerable interval between there is the doubt that the second affection may not have been epidemic influenza. We may, however, suppose that a brief immunity was obtained before the disease was again contracted. That natural immunity exists is beyond doubt; for example the author treated patients during both pandemics yet never contracted the disease. In order to visualize the operation of the pandemic let us imagine many people closely crowded together who chance to be pneumococcus carriers. The influenza virus smites them and a murderous epidemic follows. One carrier of grippe virus is enough to start the trouble and he may not be ill at the time. In some of the villages in Valais whole families were wiped out, although up to a certain date influenza had been mild. Autopsies and cultures showed that death was due to the pneumococcus. For the complete family invasion to occur doubtless there was mouth transmission and much disease and death could have been prevented by intrafamilial prophylaxis, as has been abundantly shown in different countries. Among measures for treatment the author has found excellent results from small doses of brandy added to the milk of the diet.

Epidemic of Rabies in Paris.—Martel calls the attention of the Academy of Medicine to the epidemic incidence of rabies in Paris and vicinity. Since its recrudescence in 1915 the number of animals known to have been affected is 411. A number of human cases have occurred after an immunity in the city of 12 years. The proportion of dogs who are at large without leash or muzzle and without the regulation collar is nearly as large as that in which the legal forms are obeyed. The indications are to enforce the laws and destroy the surplus of animals. If the collar ordinance is enforced the homeless animals can readily be identified.—*La Presse Médicale.*

Book Reviews.

A Hand Book of Colloid Chemistry. The Recognition of Colloids, the Theory of Colloids, and Their General Physico-Chemical Properties. By Wolfgang Ostwald, Privatdozent in the University of Leipzig. Second English Edition Translated from the Third German Edition by Martin H. Fischer, Professor of Physiology in the University of Cincinnati. With numerous notes added by Emil Hatschek, Cass Institute, London. With 63 illustrations. Price $3.50. Philadelphia: P. Blakiston's Son and Co., 1919.

As the translators and revisers of Ostwald's Colloid Chemistry say in their preface to the present edition, it is a difficult and a delicate task to make a revision of a book when the author thereof is alive in another country. However, Dr. Martin H. Fischer and Emil Hatschek have met the difficulty in the best manner possible by leaving entirely untouched those large portions of the volume which contain the author's individual views. Moreover, the work has been brought up to date by the addition by Hatschek of numerous paragraphs dealing especially with the mechanical properties of colloids, with their viscosity in particular. It is superfluous to emphasize the importance of colloid chemistry—this is self-evident. Ostwald's work presents the subject fully and clearly, while the translation by Dr. Fischer is excellent.

Oxford Loose-Leaf Medicine. In Five Volumes. Edited by Henry A. Christian and Sir James Mackenzie. Volume I, Part I. New York: Oxford University Press, American Branch.

The object of the publication of this series of papers is mainly to bring treatment into line with recent advances in pharmacological knowledge. That is to describe what is deemed to be proper treatment in more exact terms, to advise methods which seem likely to give results, and to discard many drugs formerly recommended, not necessarily because they have no value, but because at present we do not know their real value or their method of action. In short, to advise as far as is possible the administration of drugs concerning which we possess definite and accurate knowledge as to their therapeutic value based upon their mode of action. Of course, there are drugs the usefulness of which has been demonstrated by long clinical experience, and these will be recommended. But in the main, the aim of Oxford Medicine, as stated in the introduction, will be to aid in the inauguration of a really specific drug therapy.

In Vol. I, the general story of modern medicine will be told and explanations will be given of exactly why change is taking place in our views as to disease. In Part I, Vol. I, Present Day Medicine is sketched by Dr. Henry A. Christian of Boston, who together with Sir James Mackenzie of London is editor of the new work. The Future of Medicine is dealt with by Sir James Mackenzie. The Heritage of Modern Medicine is discussed by Dr. William B. Johnston. Chapter I, The Part Played in Diet by Foods of Unknown Chemical Nature is contributed by Dr. Elmer V. McCollum, and Chapter II, Climate in Relation to Health and Disease by Dr. Henry Sewall.

If the term Anglo-Saxon is applicable to the two great English speaking races, and even if it be not strictly appropriate or correct ethnologically, it is at least easily comprehensible, Oxford Medicine is essentially an Anglo-Saxon undertaking. The editors are respectively a well-known American physician and a distinguished British physician, while the contributors to the volumes are eminent American and British medical men. The scheme of this new departure in medical literature is excellent. The contents of Part I, Vol. I, augur well for its future. It is an outcome of the war in that it advocates and assists in the reconstruction of medicine, and its publication is significant of the amity and good feeling existing between the Anglo-Saxon medical professions on either side of the Atlantic.

It should be said that the Oxford Loose-Leaf Medicine marks an epoch in the publication of medical works. By adding new leaves which will be furnished at regular intervals, the work may be kept up to date. The binding ingeniously lends itself to the incorporation of the loose leaf in a simple and convenient manner. The trouble in all works published after this system is that the owners often neglect to insert the loose leaves when they are received and, even if they do, they neglect to read the article again, and so fail to profit by the revision.

Studies in Electro-Physiology (Animal and Vegetable). By Arthur E. Baines, Consulting Electrician, Author of "Electro-Pathology and Therapeutics," etc. With thirty-one original drawings in color, illustrating the electrical structure of fruits and vegetables. By Gladys T. Baines, and numerous other illustrations. Price $5. New York: E. P. Dutton & Co.; London: George Routledge & Sons.

In the pages of this book Mr. Baines sets forth in clear language his belief or theory that the human body is designed for electrical functions, or rather he endeavors to show, judging from its structure, that electrical action in the body is precedent to chemical change. The author is a distinguished electrician. He was associated with Prof. Andrew Jamieson in cable repair work in the Red Sea and Indian Ocean, and became editor of the *Electrical Engineer*. The book is a most interesting presentation of views which are novel and almost revolutionary. The illustrations are original and excellent.

A Doctor's Discovery, or The Elixir of Life. With Appendices on Fasting and Cooking. By John Haddon, M.A., M.D. (Edinburgh). Price 3/6. Edinburgh: Published by the Author, 1918.

Dr. Haddon for many years has written on vegetarianism and the benefit to health of eating sparingly. Moreover, the author has practised what he preached and declares that personally he has proved that such a mode of diet is the true elixir of life. The book is well and interestingly written and a good deal of the advice given might undoubtedly be put into practice with advantage by perhaps the majority of people.

The Surgical Clinics of Chicago. Vol. II, No. 5, October, 1918. Octavo of 194 pages with 87 illustrations. Published bi-monthly. Price per year, $10.00. Philadelphia and London: W. B. Saunders Company, 1918.

This issue of the Clinics, while a little short on pages, is long on value per page; in fact, is one of the best numbers that has appeared. There are eleven contributors and nearly all have presented material that is well worth reading. It is hard to pick out sections for special commendation without doing an injustice to others perhaps equally good but of more interest to those specializing in other lines than the reviewer. Bevan presents clinical lectures on five cases all of which are very instructive. Eisendrath concludes the clinical lecture on "The Acute Abdomen," which was begun in the previous number, here taking up lower abdominal conditions and ending with a description of the findings in the case which suggested the topic. Eisendrath's complete article on the acute abdomen, covering conditions of both upper and lower abdominal organs and filled with comment based upon his long experience in abdominal surgery, is very instructive and, with some further elaboration and illustration, deserves reprinting in book form so that it may be available to a larger circle of readers. Mix gives an interesting talk on gastric carcinoma. Printy describes what he calls "A Perfected Technique for Posterior Gastroenterostomy and for Cholecystotomy." The reviewer disagrees regarding the "perfection" of the technique. The author describes what is undoubtedly a good technique, but it seems no better than that described by various other writers and in common use, while it is much more complicated and time-consuming than most of them. In the reviewer's opinion the time to announce a "perfected" technique has not yet arrived. Bernstein presents an improved technique for tendon transplantation, which seems to us to follow rather closely that of Leo Mayer. The other contributors are Moorhead, who presents three cases of exstrophy of the bladder; McKenna, Watkins, Reed, Parker, and Ochsner, each of whom presents one or more interesting clinical cases with appropriate discussion. Most of these latter contributions deserve special comment.

Society Reports.

INTERNATIONAL CONFERENCE ON REHABILITATION OF THE DISABLED.

An International Conference, on a wide scale, dealing with the treatment of the disabled from wounds and disease was held at the Waldorf-Astoria Hotel, New York, March 18 to 21, inclusive. The conference was truly international and the discussions thereat were chiefly concerned with the rehabilitation of those disabled by war, but the matter of disablement in civil life was also dealt with. The governmental authorities of the principal allied countries sent official delegates and there were thus represented the French Ministry of War, the Belgian Ministry of War, the Italian Ministry of Pensions, the British Ministry of Pensions, the British Ministry of Labor, the Canadian Department of Soldiers' Civil Reestablishment, and the Canadian Department of Militia and Defense. France was represented by Dr. Maurice Bourillon, president of the Comité Permanent Interallié, director Institut National Professionel des Invalides de la Guerre; Belgium by Louis Alleman, Chief of the Educational Staff, Institut Militaire Belge des Invalides et Orphelins de la Guerre; Great Britain by Mrs. Ethel Wood, secretary of the Local War Pensions Committee, London, Capt. Percy G. Sharp, in charge of the curative work at Shepherd's Bush Military Orthopedic Hospital, London, and Major Francis Meynell of the Ministry of Labor; Italy by Professor Vittorio Putti, director of the Rizzoli Institute, Bologna; and Canada by F. Gerald Robinson, Department of Soldiers' Civil Reestablishment, and W. E. Segsworth, director of Vocational Training, Department of Soldiers' Civil Reestablishment, Ottawa. Among the American official establishments represented were the office of the Surgeon-General, U. S. Army, the Federal Board for Vocational Education, and the American Red Cross.

The conference was arranged under the auspices of the Red Cross Institute for Crippled and Disabled Men and the Red Cross Institute for the Blind.

To Mr. Douglas C. McMurtrie, the director of the Institute, was largely due the credit for the initiation and development of the conference.

The program presented was so full that it would be impossible in a limited space to discuss even briefly the principal addresses. Some 300 papers were read. Therefore only the papers which bore most directly on medicine or surgery will be commented upon.

The opening address was given by Dr. Maurice Bourrillon, the subject of which was "National Organization of Rehabilitation for the Disabled in France." The speaker briefly reviewed the work in the direction which has been undertaken in France since the beginning of the war, paying especial attention to the measures taken to rehabilitate the disabled after their wounds have begun to heal and they are preparing to take their places in civil life. He told of the methods employed at Saint Maurice to render disabled men self-supporting as far as possible and described the efforts of medical men and surgeons to make such men physically and mentally fit. As for measures of education and vocational training he pointed out that it was not enough to determine what trade is most suitable for a man's general state of health and particular disability. One must consider also whether this trade corresponds to the mental powers and capabilities, and to his own preference and manner of living, for it is often unwise to place a man outside his class. Before deciding definitely in favor of any occupation, it is always safe to ask oneself these two questions: *First*, does the proposed occupation guarantee the disabled man a sufficient wage, with the minimum of fatigue and danger, to enable him to live honorably and steadily for the rest of his life? *Second*, is there not some other occupation which would offer even superior advantages under analagous conditions. Dr. Bourrillon drew attention to the fact that according to official figures French casualties up to November 4, 1918, were 34,300 officers and 1,351 soldiers and sailors killed or missing and 694,000 incapacitated by disease or wounds.

L. Alleman gave a graphic account of the manner in which Belgium is grappling with the problem of caring for and at the same time reeducating and training her disabled soldiers. All the speakers from Europe laid particular stress on the point that as many men as possible should be trained to work on the land. Mr. Alleman described in some detail the work that is being done at Port Villez, the Belgian military institution at which he is the chief of the educational staff.

Mrs. Ethel Wood of London told of what England is doing in the way of national organization of rehabilitation. Mr. F. Gerald Robinson and Mr. W. E. Segsworth performed a similar service for Canada.

On the afternoon of March 18 the work of the Division of Physical Reconstruction of the office of the Surgeon-General, U. S. Army, was related by Dr. Frank Billings. Among other facts brought out by the speaker was that up to the time of the signing of the armistice 85½ per cent of wounded American soldiers were returned to the battle front while another five per cent were treated with sufficient success to allow of them being assigned to limited service groups. In the neighborhood of 10,000 men were transported to this country for further treatment, signifying that less than 10 per cent. were regarded as injured seriously. Dr. Billings largely attributed these remarkable results to the directions given by the Surgeon-General's office in regard to vocational training and curative work in hospitals abroad. He pointed out that when hostilities ceased there were 92,000 Americans in French and British hospitals. Since then 80,000 had been brought home for treatment. He said that physical therapy on curative work at the present time is being carried on in forty-eight hospitals under the direction of the Division of Physical Reconstruction and that 17,000 disabled soldiers are being treated by such methods. The speaker emphasized the great importance that the public must play in the rehabilitation of the disabled. Public opinion must be exerted to its fullest extent upon relatives of wounded soldiers to convince them that unless their loved ones remain in the army hospitals long enough to ensure complete mental and physical cure, the work of the entire treatment would simply be time wasted. In the view of the speaker, play was a most important part of curative treatment.

During the evening of March 18 the American program of vocational rehabilitation was discussed.

Dr. Charles A. Prosser, director of the Federal Board for Vocational Education, sketched the U. S. Government program for vocational education. In June, 1918, by the Vocational Rehabilitation Act, Congress turned over to the Federal Board of Vocational Education, which had been in existence for some time, the entire task of reeducating and placing in employment the discharged soldiers, sailors and marines who have been so disabled that they are entitled to compensation from the War Risk Insurance Bureau and need the help of reeducation and placement in order to "carry on" successfully in the pursuits of civilized life. There was no necessity in this country as there was elsewhere for public-spirited citizens to interest themselves in the matter, to build workshops and schools and care for the men. The Federal Board took the problem in hand without the least disorganization of existing machinery. According to Dr. Prosser about 200,000 men will require retraining. Of this number about half have been crippled by wounds and half disabled through sickness. Three thousand six hundred are still in France and the remainder have been transported back to this country. Nearly 40,000 have registered already with the Federal Board asking for help. An analysis of the first 1,200 cases showed that 245 men out of that number selected agriculture, 274 commercial pursuits, 372 industry and trade, 275 professional, 45 courses in Americanization and 22 unclassified.

On the afternoon of March 19 the vast subject of vocational education was discussed. The first paper read was by Dr. André Treves. Dr. Treves said that from the very beginning of the war the French Army Medical Service had concerned itself with the question of the functional reeducation of the wounded. A ministerial circular, dated December 31, 1914, ordered simultaneously the organization of "centers," or hospitals, of orthopedic surgery, and centers of functional reeducation, which in France are termed centers of physiotherapy. The physicians-in-chief of these centers were independ-

ent of each other, but often worked together. They often made tours of inspection in the same automobile through the districts dependent on their centres and together looked up the wounded who should be directed to their respective hospitals. Each week they met at the centre of physiotherapy, examined together their wounded, decided whether the treatment should be surgical or functional restoration, and in this manner conducted a constant exchange of patients. The French Government has made liberal appropriations to its departments of physiotherapy and has installed all the necessary methods of treatment. Also, thanks to her wealth in mineral waters, France has been able to give her wounded the benefit of those valuable therapeutic measures. In the course of the year 1915 numerous subcentres of functional reeducation and radiology were created in order to avoid too much transferring of the wounded. These subcentres remain under the control of the physician-in-chief of the main centre. Dr. Treves laid much insistence on the point that the early use of the temporary appliance for amputation stumps hastens the time when the man can be furnished with his permanent appliance, the so-called American leg. The speaker declared that French medical men are of the almost unanimous opinion that physical work constitutes the best kind of mechanotherapy, the best functional reeducation. Like all the French medical men, Dr. Treves is greatly in favor of readapting disabled men to farm work, and he deals with this question in another paper which will be discussed later on.

The next paper read was by Capt. P. G. Sharp of Shepherd's Bush Military Orthopedic Hospital, London. The speaker emphasized the value of occupational work for the men while they are still in hospitals, arguing that when the disabled man is given some interesting occupation while he is in the hospital undergoing treatment, it not only serves to restore his functions, but also gives him confidence that he can do useful work again, and thus encourages him to make a fresh start. Captain Sharp is a strong advocate of curative workshops, that is, the system of treating a man's disability by physical therapy provided in the form of various kinds of handicraft. It is contended that in addition to exercising the disabled members, it is of very considerable psychological value, because it is interesting and useful. The system is in vogue at Shepherd's Bush and in the majority of the British Military orthopedic hospitals.

Dr. R. Tait McKenzie read the next paper, which had for its theme medical gymnastics and occupation. Professor McKenzie, while admitting freely that curative workshop work was beneficial and highly to be commended, deprecated the view that mechanotherapy was comparatively useless, because it was monotonous and uninteresting. He pointed out that curative work did not always exercise the parts affected properly. It exercised them sometimes in a harmful manner. He said that mechanotherapy was not opposed to curative workshop methods, but that one should be regarded as an adjunct of the other, or rather, that they should be coordinated. All forms of physical therapy were of value when employed intelligently, but in McKenzie's opinion curative work should not be relied on solely, but used in cooperation with mechanotherapy and other forms of physical therapy.

Capt. A. E. Bott of the Military School, Hart House, Toronto, Canada, read a paper on training lay workers for functional restoration. Captain Bott is a follower of Dr. McKenzie, and believes in mechanotherapy. He pointed out that the lessons learned in the war would be useful in civil life, and that this statement applied, of course, to physical therapy. He suggested that lay workers should be trained in physical therapy and said that judging from his experience women were, on the whole, better than men. They were more patient, and more careful as to details. He was of the opinion that intensive training in physical therapy was of little use nor did lectures impart the necessary knowledge and skill. Two hours a day for a time was sufficient, and it was better to teach in classes of not more than eight. He pointed out that while physical therapy was as important in peace as in war, it must be borne in mind that conditions were very different. In order to apply the lessons learned in war concerning the value of physical therapy there must be a supply of competent teachers. At present there were not nearly enough of skilled teachers, and therefore it was essential that the careful teaching of those who offered themselves and possessed the requisite qualifications should be made the matter of consideration.

Dr. W. Gilman Thompson of New York discussed mechanotherapy and occupation. He said that in this country they had received their inspiration, so far as physical therapy was concerned, from McKenzie and Bott. He agreed that exercise to be therapeutically most valuable should not be monotonous, but argued that mechanotherapy need not necessarily be monotonous. As an example of mechanotherapy being rendered interesting he pointed to the apparatus designed and devised by McKenzie and Bott, which fulfills the dual conditions of being both interesting and therapeutically of great service. By this apparatus energy can be measured in reaching an object, and also skill must be exercised in bringing the movements of the machine back to rest. It supplies a means of competition which makes it interesting and at the same time exercises those parts which require physical therapy in a more certain and exact manner than can be attained by curative work. In short, according to Thompson, in curative workshops the necessary exercise cannot be accurately gauged or regulated, whereas with Bott's apparatus this can be done. One is empirical and the other scientific. In another section of the meeting in the afternoon of March 19, the encouragement of men to undertake training was discussed.

M. Edmond Drousart, Director of the Ecole Professionelle des Blessés Montpellier, France, dealt with the problem of how to encourage disabled men to take training in those countries where such reeducation is not compulsory. He pointed out that the number of disabled men in France who enter the vocational schools is at the present time insufficient. To attain this end two important means are employed: (1) Bring the organization of the schools to the highest possible degree of perfection, so as to secure the full confidence of the disabled and to make the residence at the schools as attractive as possible. The speaker said that this program had been fully carried out in France, and that the American Red Cross and, in particular, Miss Grace Harper, who has been directing the Bureau of Crippled Soldiers in Paris, had been of greatest assistance in the accomplishment of the task. M. Drousart suggested that the conference recommend that propaganda in favor of reeducation shall be intensified in all allied countries. In the opinion of the French medical profession this was the most important problem of the present moment.

(To be continued.)

BRONX COUNTY MEDICAL SOCIETY.

Stated Meeting, Held February 19, 1919.

The President, Dr. Isaac M. Heller, in the Chair.

A Case History from Willard Parker Hospital.—Dr. I. H. Goldberger reported this case, which presented a problem in diagnosis. The patient was a boy sent to the hospital as a case of influenza, with the history that he had been running a high temperature for four days before admission. At this time he was running an up and down temperature between 102.5° and 99° F.; his pulse was 100, and respiration 24. The temperature continued to rise and fall for the next three days, when it was decided that this was not a clear case of influenza, especially as there were no pulmonary signs demonstrable. On the seventh day after admission a petechial rash appeared more prominent on the abdomen and somewhat resembling the roseola seen in typhoid fever. The temperature continued to rise and fall, and on the ninth day there was a sudden chill. The differential blood count was 12,200, the Widal test was negative, and several examinations of the blood for plasmodia were also negative. The up and down temperature continued for five or six days longer without any physical signs appearing to account for it. The Wassermann was negative. On the fourteenth day the patient complained of rigidity of the neck, but it was not the rigidity of meningitis. There was a slight Kernig sign. A lumbar

puncture was done and the spinal fluid was found to be under extreme pressure. After withdrawing 30 or 35 c.c. of spinal fluid a red tinge was noted and the flow stopped. Dr. Neal examined the fluid and found it negative. Blood cultures were also negative. At the end of 24 hours 15 or 20 c.c. of spinal fluid was again withdrawn and was negative. Several subsequent punctures also proved negative. After the lumbar puncture the headaches from which the patient had been suffering disappeared, the temperature remained normal, and recovery ensued. This case was undiagnosed, though they took into consideration the possibility that they were dealing with influenza of an atypical type. The very slight turbidity of the spinal fluid was considered to be due to the prolonged high temperature.

Dr. J. LEWIS AMSTER asked for further details in reference to the spinal fluid.

Dr. GOLDBERGER replied that the fluid showed an increase in cells, the bacteriological examination was negative, albumen 3, and Fehling's 2 plus. The rigidity of the neck disappeared immediately after the spinal puncture.

Hospitals in the Bronx.—Hon. JOSEPH CALLAHAN made a brief address on the urgent need of hospital facilities in the Bronx, in which he said that he had at one time thought that State legislation might be an aid in getting the new institutions that they needed, but after due consideration he had come to the decision that such action was not necessary. He was in favor of borough autonomy and felt that it would be better to have their hospitals under the State Board of Charities rather than as a part of the Bellevue and Allied Hospitals. The speaker discussed the prospects for getting city money and declared that while there were difficulties in the way this was not altogether a forlorn hope.

Report of Committee on Hospitals.—Dr. J. LEWIS AMSTER read a report showing the exact hospital situation in the Borough of the Bronx, in which emphasis was placed on the fact that undernourishment was recognized as leading to tuberculosis, influenza and pneumonia, and that the high price of food had resulted in much undernourishment among the poor, in consequence of which there was a greater demand for hospital beds at the present time than ever before. In addition, the lack of hospital facilities was felt more keenly, because of the returning soldiers requiring hospital care, which made it necessary to turn over for their use many hospital beds that under ordinary conditions would be for the use of the civilian population. The report gave detailed statistics in reference to the hospitals of Manhattan and the Bronx, and showed that in Manhattan there was one hospital bed for every 250 persons, while in the Bronx there was only one for every 600 persons. This lack of hospital accommodations, evident at the time of the poliomyelitis epidemic, was much more keenly felt during the recent epidemic of influenza. The most pressing needs were for a contagious hospital, as patients suffering from a contagious disease had to be transported to Willard Parker Hospital, which was much too long a trip, a municipal hospital in the lower West Bronx, and one in the upper western section. At the present time the staffs of their hospitals were composed almost exclusively of Manhattan physicians, whereas they should consist largely of Bronx doctors. The report also called attention to the need of districting the ambulance service.

The Cancer Problem.—A Chapter in Medicine.—Dr. ISAAC LEVIN read this paper. (See p. 551.)

Dr. ROBERT T. MORRIS stated that if some of the points made by Dr. Levin were aligned for purposes of a logical sequence leading toward a deduction, several questions might be introduced with propriety. Let us take these three points: Smith had shown that cancer in plants appeared to depend upon the presence of a microbe. Dr. Levin had shown that cancer in chickens might be induced by the injection of a filtrate made from cancer material. Other investigators had shown that in white rats cancer developed only under certain conditions relating to nutrition. Might we not find some common divisor for these three factors in the problem? Let us postulate that the microbe in plant cancer furnished an enzyme, that the filtrate described by Dr. Levin furnished an enzyme, and that defective metabolism furnished an enzyme. Let us assume that three different kinds of enzymes had one common action in exciting a cell into abnormal activity. What was this cell which was excited into activity? Was it a cell representing arrested development? We had arrested development of structures; why not arrested development of a cell? According to the Cohnheim theory, latent embryonic cells remained inactive until excited into activity by some agent. Perhaps arrested development of a cell later in the life of an individual might result again in the production of a cell of embryonic type. Let us stop for a moment to consider the point that a perfect ovum and a perfect spermatozoon as two gametes made a zygote which went on to the formation of a perfect being. A cell with arrested development on the other hand, might start off individually to make its own kind of structure by haploid division, the latter mass of tissue constituting cancer. If a number of different enzymes acted as stimuli forcing our hypothetical haploid cell into activity, we might then ask under what circumstances such cells occurred in individuals in the animal world or in the plant world. Let us ask another question. Did the cancer in plants occur in cultivated plants only or in wild plants? Cancer experiments with animals had related chiefly to cultivated animals. Under conditions of cultivation, where the element of struggle was removed in greater or lesser degree, individual cultural limitations were reached, and when cultural limitations were approached we had the appearance of arrested development of various structures. This influence finally resulted in the disappearance of that group of cultivated varieties of plants or animals. Cultural limitations were being approached among various civilized peoples at the present time, and in these groups one might anticipate an increase in cancer as a result of arrested development of certain cells very much as we found arrested development of structures made up of cells. Under such circumstances we were not to look for the exciting cause for cancer so much as we were to look for the kind of cell development which permitted various influences to set cells of embryonic type into active proliferation. The successful treatment of malignant disease with radium or the *x*-ray perhaps included the idea that normal cells in the vicinity of the malignant growth were whipped up into an activity which gave them increased protective power against invasion by our hypothetical haploid cell. The selection of the expert who was to use radium or *x*-ray became a very important responsibility, and the work that Dr. Levin had done for some of the speaker's patients had been very satisfactory.

Dr. MAX EINHORN said that while he hardly felt able to discuss the etiology of cancer he might speak in regard to the treatment. The first point was that the earlier cancer was recognized the better was the prospect that something might be done. Another point was that the more superficial the growth the greater the degree of success one could expect. This was evidenced by the good results obtained in cancer of the breast, which the surgeon attacked very early, the reason being that it was discovered early because it was accessible. Again the more radical the operation the more cures were accomplished. In deep-seated cancer there was less hope for big accomplishments. Years ago malignant growths of the gastrointestinal tract were rarely attacked by the surgeon, and at first they were very chary of operation in this locality but later they had been more successful, and now there were some cures reported after operations for cancer of the pylorus in which the diagnosis was made after careful microscopical examination. Dr. Einhorn cited two cases of true cancer of the pylorus in which the growths were small and the entire tumor could be cut out, and these patients lived, one for a period of twelve years, when he died from heart disease. He did not think the percentage of cures in these cases could be taken as 20 per cent., for the reason that many tumors of the pylorus which appeared to be malignant were not really malignant. For example, in one patient, six years ago, operated on for a tumor of the stomach, upon opening the stomach it was found that the case was inoperable and nothing was done except to close the wound, and that patient lived. Two or three years later this patient returned suffering from hemorrhage and the tumor was no longer present. It was thought that the hemorrhage was an indication for operation and that the patient

was suffering from a severe ulcerative lesion which required surgical interference. At the operation no trace of the tumor was found. A gastroenterostomy was performed after which the patient recovered and was still alive. He evidently had no cancer at all. He could recall several similar cases in which there was no syphilis, and yet the tumor disappeared, showing that there were some growths which looked like cancer but were not. But to speak of the paper and real cancer, cancer of the colon was very favorable for treatment. Resection frequently accomplished a cure and in many cases he had seen patients live six, seven, and eight years after a partial resection of the colon. It seemed that the disease did not spread out so quickly in this location and if one got the cases early while the cancer was still localized there was a good prospect of eradicating the disease. This might be because there were not so many lymphatics in this region. In regard to the radium and *x*-ray, it might be said that the outlook for cure by these agents was more favorable when the cancer was situated in an accessible location, as in epithelioma of the skin, which had shown a number of cures by radium. Dr. Einhorn cited an instance of epithelioma of the eyelid cured by applications of radium, in which the man had remained cured for six or seven years and there was no return. He had sent this man to eye specialists and nose specialists and all said that nothing could be done for him, that they would not operate, so he thought he should be given the benefit of the radium applications, as a result of which he had recovered and his nose was perfect and the eyelid all right. Radium could be applied to many kinds of cancer situated in other organs if the disease was discovered early, was still localized and the influence of the radium could be brought to bear on the whole field of the affection. It was not so easy to apply radium to deeply situated organs. A few years ago he had tried to treat cancer of the esophagus with radium in a case in which it seemed that the radium could be placed exactly at the site of the growth, but it did not result in a cure and he had not thus far seen a cure in a case of that kind, though great relief might be afforded the patient, and that was a matter of great importance to the physician. One could not tell these patients that they were going to die so the physician should do what he could to make the life of such patients bearable, and radium did much to alleviate the suffering in these cases. He had found that one-half of the cases of malignant stricture of the esophagus were improved by radium treatment. In as far as these cases were inoperable, one was entitled to try a remedy even if a radical cure could not be promised. He had found that in about 50 per cent. of these cases the condition of the patient was greatly alleviated, so that he could eat better and the esophageal canal was widened, and life prolonged. In cancer of the stomach in which operation could not be performed because the patient could not stand it, he had found that the introduction of radium had caused a cessation of the hemorrhages, and the patients were more comfortable and lived longer. In a patient with stricture of the pylorus he had succeeded in applying the radium to the spot and he did not doubt that it had prolonged life, and that was a great deal. For these reasons he congratulated Dr. Levin for his efforts in showing what radium and the *x*-ray could do in malignant disease, and he hoped more would take advantage of these means for the alleviation it afforded in this most severe disease of the human race.

Dr. Henry Roth said that he felt that the cancer problem was a very serious one, even if it was not hopeless. In spite of the fact that many patients lived over five or ten years after the removal of a malignant growth it was nevertheless a fact that in a large percentage of cases little can be done to save the patient from early death owing to the advanced stage of the disease. Complete eradication of the disease was only possible while it was still a localized condition. He wished to enter a protest against some of the articles which had appeared in medical journals stating that cancer was a systemic disease amenable to certain forms of diet and required no operation. Such teaching was pernicious, dangerous, and almost criminal, and how it could ever get into medical literature was hard to understand, and yet he had only recently seen such an article in one of the leading journals in this country. Another recent article stated that cancer was a general disease and that the tumor was only a local manifestation of it, and that the condition should be treated by diathermy and not by operation. He wished merely to repeat what Dr. William J. Mayo said some years ago, namely, that there was no authentic case of carcinoma of the stomach on record which had been cured by any therapeutic measure other than surgery. When one heard of cancers cured by measures other than the surgeon's knife or radium, careful investigation would usually prove them to be cures of conditions called cancer but not true cancers. To-day there were only two measures which could be relied upon to effectively remove cancer, and these were the surgeon's knife and radium. Basal cell epitheliomas, for instance, were known to disappear promptly under radium or roentgen ray treatment. He believed that to bring about an improvement in the cancer situation we must avail ourselves of all known means to recognize the disease at the earliest possible moment. He was furthermore of the opinion that considerable benefit could be gained by educating the public to seek proper advice soon after the appearance of certain symptoms and signs. People should be taught the importance of the early recognition of cancer and they should be impressed with the fact that neglect to get proper treatment at the proper time meant a fatal outcome. People should be educated to consult a physician at the earliest possible opportunity after the discovery of a new growth in any part of the body and not to go about hiding it, as many of them had done in the past. He was deeply impressed with the fact that cancer in a young person was extremely serious. For instance, cancer of the breast in a woman under thirty-five years of age was so serious that he felt safe in prognosticating that few such patients would live over a year even after a radical operation. Such cases usually developed metastases in the bones, especially in the spine, femur, and humerus. The results in cancer of the colon were rather gratifying; he had known of a number of patients living five years and longer after operation. Dr. Einhorn had spoken of the improvement brought about by radium in cancer of the esophagus. The same could be accomplished by a gastrostomy with the additional advantage of being able to give the patient the necessary amount of food, and thus prevent death from starvation.

Dr. Seymour Basch said it seemed to him that the meeting had been a symposium on unsolved problems; first the case for diagnosis, next the need for hospital facilities in the Bronx, and finally the cancer problem, which would probably remain an unsolved problem for some time. Dr. Levin had discussed the theoretical phases of the problem and as most of the men present were practitioners and did not have the technical training necessary to discuss these theoretical problems he felt that this was not the place to go into detail in regard to the underlying problems. As Dr. Levin had referred to the bacteriological problems it might be interesting to mention that D'Arcy Powers had published an article showing that environment had something to do with the development of cancer. The fact brought out that some persons seemed to have a natural resistance to cancer seemed to favor the bacteriological theory. As to the illustration of the secondary cancer in the brain produced from the cancer in the rectum, he would like to know if what Dr. Levin had said of that was true of all metastases; he did not think so. The question of diagnosis and therapy was the most important to all practitioners, particularly the early diagnosis of cancer. The surgeon usually dealt with cancer in its more advanced form, and if he frequently made an incorrect diagnosis, how was it to be expected that the practitioner who saw these cases at even an earlier stage was going to make the diagnosis. Cases of erroneous diagnosis, such as those cited by Dr. Einhorn, were multiple, and if it was so difficult for the practitioner to make the diagnosis how much more difficult must it be for the layman? When the layman was really in danger he frequently would not consult the physician. On the other hand there were many patients who did not hide their fears and who came to the physician oftener than was necessary when there was no ground for fear. With the ex-

ception perhaps of the breast and certainly of the uterus, he did not think with Dr. Roth that many hid their fears because they were prudish until after it was too late to operate. Another point that should be emphasized was that the only proper diagnosis was the microscopical diagnosis. The miraculous cures were those that occurred in the cases of clinical cancer, for when those growths were submitted for laboratory examination they turned out to be innocuous. Again, there was nothing more misleading than statistics. Frequently cancer was omitted from the death certificate to spare the family the anxiety that might follow the knowledge that the disease was in the family, and at other times when the physician did not know the diagnosis he would call the case cancer. That class of cancers of the pyloric region in which Dr. Lilienthal did the operation in two stages brought out interesting phenomena. He first did an exploratory operation and a gastroenterostomy, and later when it came to the second or radical operation it had frequently been found that the so-called "cancer" had disappeared. Only very recently, too, he had seen a case that was operated on by Dr. Roth, and thought to be an indurated ulcer turned out to be a sarcoma. As to radium, it acted through two kinds of rays, the destructive soft rays and the stimulative or hard rays which penetrated deeply and possibly led to cell proliferation. That was the reason he had spoken against the use of these rays in deep-seated growths, for, while the rays might destroy the superficial cancer cells, they might also stimulate the deep cells to more active growth. Febiger had demonstrated that a cancer like tumor in rats could be transmitted by the ordinary roach, which carried the virus, and that this virus was shown to be present in primary growths but not in secondary growths. Did not that speak for the parasitic origin of cancer? He would like to ask whether Dr. Levin had made any experiments with thorium and whether he considered it of definite value in the treatment of carcinoma. In this city two men, Klein and Walker, claimed that carcinoma was of chemical origin, and believed that it could be combated by chemical means. They also believed that a diagnosis of carcinoma could be made by urinary examination. This brought up still another question in the carcinoma problem.

Dr. Abraham Lightstone said that, speaking from the standpoint of the surgeon, he wished to emphasize a few points. First, no matter how forcibly it was impressed upon the physician that an early diagnosis was a necessity it was surprising how many cases continued to walk about in which there was no question but that a cancer was present, and this class of patients were very much neglected. As an example he had a case a few months ago in the Fordham Surgical Clinic, a woman 30 years of age, who had a baby fourteen months old, and who had a lump in her breast which was noticed during her pregnancy. She was examined by several doctors, who told her that the lump would disappear after the child was born. Dr. Lightstone had performed a radical amputation of the breast, and said that Dr. Schwartz, who made the pathological examination, pronounced the growth carcinoma. This was a clear case yet it was not diagnosed. Another form of cancer frequently not diagnosed was carcinoma of the rectum, patients with this condition frequently being treated for stomach trouble, piles, etc., when an examination of the rectum would reveal the presence of a malignant condition. The speaker cited another case in which a diagnosis of ectopic pregnancy was made and at operation he found a tumor of the ovary which Dr. Jeffroes had pronounced a sarcoma of the ovary. In a case that looked like carcinoma of the cervix uteri he did not even wait for the pathologist's report but removed the uterus at once, and he was convinced that that was the proper procedure, as the possibility of recurrence was thus greatly diminished. So far as mistaken diagnoses of cancer were concerned he thought the greatest mistakes were made in gumma of the viscera, and in cases of this kind the tumor had been known to disappear. Such a case was cited by the speaker, who called attention to the fact that polyps of the rectum were frequently mistaken for carcinoma and that even pathologists sometimes failed to differentiate these conditions, as it was exceedingly difficult at times to make the distinction between benign and malignant neoplasms by the microscopical examination of small pieces taken from the growths.

Dr. Joshua Leiner suggested that all disease was simply a manifestation of abnormal physiology, and further, that a biochemical reason might therefore be the basis for the cancer problem. Was it not a fact that the endocrine system controlled the biochemistry of the human body, which in turn led to the "general reaction make-up" of the individual, namely, either vagotonic or sympathicotonic, or to a cancer reaction due to a disturbed endocrine system? As for example, as Dr. Levin said, the testes had to be irritated (chemical change) before the cancer cell could find the proper media for proliferation. This hypothesis would explain why 90 per cent. of the human race was immune from cancer and 10 per cent. were attacked. For instance, the thyroid had an enormous influence on the metabolism and growth of the human body, purely through the media of biochemistry. W. W. Swingle, of the Department of Biological Chemistry of Princeton University, experimenting with the larvae of the common leopard frog, fed cultures with an iodine paste. The results of the experiments appeared to indicate very strongly that iodine was the activating principle of the thyroid gland, and that this substance functioned within the organism as a hormone without the intermediation of the gland itself. Iodine feeding brought about a metamorphosis in those thyroidectomized frogs in an abnormally short time. If this process went wrong then we would have a perverted physiology. (*Endocrinology*, Vol. 2, Serial 7.) The works of Senator, Iscovescu, Leopold-Levi, De Rothschild, Hertoghe, and others had shown that the thyroid had a multiple function and was not single in this respect. The iodine took care of the general metabolism. Phosphorus took care of the thermogenesis of the body, vasomotor, cardiac rhythm, etc. The sulphur component took care of the nutrition of the skin and hair. This showed the manifold function of the organ and it was under the influence of the "endocrine confederacy." T. Brailsford Robertson, of the University of California, working on the cancer problem from the standpoint of endocrinology, started from the premise that the anterior lobe of the pituitary was associated with gigantism or acromegaly, according to the age of the individual. He studied the influence of this extract on the growth of carcinoma in the rat. He isolated an extract which he called tethelin, which acted similarly to the anterior lobe itself. This substance was a lipoid just as the lipoids in the thyroid. It stimulated the epidermis and the hair function as shown in the hypertrichosis seen in hyperpituitarism. Taken in connection with the stimulating action of tethelin on carcinomas, it would seem that it had a specific action in stimulating epithelial growth. (*Jour. Biol. Chem.*, 24, 397, 1916.) He believed this kind of work would bring us in a great measure toward a solution of this problem which was one of the most difficult and mysterious in medicine.

Dr. Levin, in closing, said that the gentlemen that discussed his paper evinced a great interest in the physics of radioactivity, but that it would be foreign to the subject of his paper to present this phase of the matter. The problem mentioned by Dr. Morris was also somewhat too theoretical to discuss before an audience of medical practitioners. Dr. Einhorn was himself apparently an active worker in radiotherapy and no exception could be taken to any of his remarks. It might be correct, as Dr. Roth stated, that it would be beneficial if the lay public were better educated in the early recognition of the subjective symptoms of cancer; but it was of by far greater importance for the profession to be impressed with the necessity of an early diagnosis of the disease. In the experience of Dr. Levin fully 75 per cent. of the cases of carcinoma of the rectum for instance had been either operated upon for hemorrhoids or treated with salves, while the tumor was present and not recognized. It would lead entirely too far to discuss at length the theoretical or therapeutic notions of Dr. Basch. It did sound strange though, the speaker said, when a clinician considered seriously a so-called chemical specific method of cancer therapy.

HEALTH WORK FOR COMMUNITY COUNCILS.*

BY HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

THE subject and work of Community Councils open up a very wide vista of service. The end of the war and the beginning of reconstruction emphasize all the problems and burdens of community organizations. How can the various health forces so coordinate and present their work as to make it possible and attractive for the masses of the people, organized in local Community Councils, to become real partners in the health enterprise?

Success in life in virtually all its pursuits, and happiness in any station, are conditioned on good health. Efficiency and strength go hand in hand. All local conditions should thus be made as favorable as possible to conserve individual vigor. No subject is of greater interest and importance to the people at large than public health.

How can Community Councils be made to function best in health work? Our understanding of the uses of Community Councils is to act as local centers that know and utilize all agencies for the common welfare. Thus the settlement may stand as the center for political and social activities; the public school as the educational center; the church or synagogue as the philanthropic center, and the hospital as the health center. The Community Council may act as a clearing house to coordinate these branches of social activity and see that in each individual case they function promptly and efficiently.

In this division of labor, subject, of course, to some overlapping, the Community Council should first strive to place a larger and broader work on the hospital. In calling for a wider activity, however, the hospital must have more effectual moral and financial support as a recasting of the machinery of operation necessarily calls for such help.

In possibilities of service the hospital represents one of the broadest human institutions. The treatment of disease, teaching, and research should all be combined in its operation. With reference to the latter, not only the investigation of the causes and treatment of individual diseases, but social disorders and maladjustments should likewise be considered. To attain its broadest usefulness, the hospital must serve as a sort of social laboratory in which disease and distress should be traced to their ultimate sources. Only thus can relief be made permanent and recurrence of disease prevented. In a last analysis many diseases present more of a social than a medical problem. It is only necessary to mention tuberculosis in this connection.

Our charities and relief agencies are frequently too segmental in their operation. As a result, there is too often delay and uncertainty in completing the circle of relief. In handling human distress, delay may be dangerous or even fatal. There is no institution that opens up so many questions and whose problems radiate in so many directions as the hospital. It should hence be made the source of very wide remedial efforts. There is too much specializing in charitable relief—seen in both individuals and institutions. As far as the hospital is concerned, social service and prevention are closely allied.

Let us trace some of the methods by which the hospital can more efficiently serve the community in which it is located. In a general way, the hospital may act as a center from which all the health work of the locality can radiate. It should thus aim to render a general communal service in all health matters. Not only should the sick be treated, but all the influences, social as well as medical, that tend toward illness must be investigated with an eye to prevention. This means a broad study of social conditions that make for sickness and disability in the community. This becomes necessary in order that a general knowledge in reference to future prevention may be acquired and constantly kept in mind. The problems of poverty and unemployment are closely connected with sickness, and thus the Community Council should collaborate with the hospital in their investigation and attempted relief.

Several surveys in different localities made by the Children's Bureau of the United States Government show that the curve of sickness and death among infants and little children follows very closely the curve of the earnings of the wage workers. Many years ago the writer started to investigate the relation between social conditions and sickness in connection with the children's service at the New York Post Graduate Hospital. From 1900 to 1902, 1,000 cases were studied to try and find the effect of living conditions as causes of the child's illness; 442 of the families lived in old, unhygienic tenements in which 764 dark rooms were noted, and 552 of the families did not have a living wage. In 1904, 700 families with sick children showed 304 with insufficient earnings, and in 1915-16 1,000 additional cases were investigated, and the earning capacity of the families did not show any essential improvement. The real underlying causes of the

*Read at a Conference on Community Forces and Reconstruction, held at New York, Dec. 13 and 14, 1918.

illness of these 2,700 children were bad housing, insufficient earnings, and ignorance on the part of the parents. This shows how the hospital may be utilized in a study of life conditions in a given locality, and points the way for Community Council efforts toward amelioration.

Poverty and sickness too often go hand in hand. There is a shifting and alternating relationship of cause and effect between them. It is interesting to note how this vicious circle works at different ages. Thus in adult years sickness is one of the principal causes of poverty. In a recent report of the New York Association for Improving the Condition of the Poor, the extent to which poverty in this locality is caused by sickness is shown in a startling way. Out of many thousands of dollars spent in material relief for destitute families in their homes, 96 per cent. was given to families who had to seek aid on account of the sickness or death of the wage earners. The Charity Organization Society has found that fully two-thirds of the cases of poverty it is called upon to investigate depend, directly or indirectly, upon sickness. These and other similar studies show both that health is necessary to secure a living wage, and conversely a living wage is one of the first requirements of health for the individual and the family. All these questions are of vital interest to the hospital social service worker and investigator.

Let us try and make every hospital a great *people's health university,* in which prevention, cure, and permanent reconstruction shall have a part. Public health lectures could easily be given by the staff to the surrounding population. Such topics as infant feeding and hygiene, the proper care and nutrition of growing children, the phenomena of adolescence, and similar subjects, would greatly help the parents in developing a healthy family life. The character and avoidance of various kinds of infection could be placed before people in such a way as to preserve their health. A corps of doctors and visiting nurses should be available for "follow-up" work after the patient is discharged from the hospital. This could readily be accomplished by an enlargement and reorganization of the social service departments already in existence. Many a patient relapses or falls into chronic invalidism for lack of proper aftercare. The good work of the hospital may thus be lost, because the ultimate condition of the patient does not bear out the promises of the case at discharge. A proper system of convalescent care for the poor on discharge from the hospital is urgently needed. A satisfactory district service would help local health conditions in many ways. It could first act to stimulate health consciousness in the neighborhood and then attack any specific problems that might arise. Active recreation as a health measure might be considered—the carrying over of that development of recreation that has grown so beneficial in army camps.

The wider extension of industrial hygiene, under the guidance of the Working Conditions Bureau of the U. S. Department of Labor and of the New York City Department of Health, will be important because it will interest and enlist employers and laborers alike; because the general social implications are large and obvious; because adult health education grows distinctly out of such attention to industrial hygiene.

Occupational diseases in the locality that feed the hospital can be investigated to advantage. Ther is also a large field in a study of the best method of dealing with the handicapped. Proper and saf employment for cardiac cases and other crippling conditions form a very necessary part of this work Clinics for undernourished children have alread been inaugurated in some of the hospitals. Larg dental infirmaries, such as have been started a Boston and Rochester, N. Y., do valuable work b correcting oral defects in poor children at a nomina cost.

As a background to the whole situation, referenc can be made to the high cost of food; to the im portance of trying to carry over to our civilia population the control of venereal disease bot through the study of prostitution and the admin istration of prophylactic treatment, which has bee so successful in the American Army. It would als be worth while to point out that vigorous play i the growing years has an influence on the prolonga tion of life and the prevention of degenerative dis eases; also to raise the question as to whether ou unsatisfactory organization of leisure life, throug which people get no real self-expression, may n have something to do with the wide extent of fun tional nervous disorders. A high percentage rejections for physical reasons among the youn men of the country, averaging one in four, draw by draft or volunteering in the army, gives foo for thought.

In many ways it is evident that our medic output is not what it could be with better organiz tion. Here is a rich field for the Community Cou cil to bring in the hospital and the social servi department as the natural point of contact wi the community in all health matters.

It has recently been proposed to arrange zon around hospitals according to the Community Cou cils of National Defense for the operation of these health activities. This movement was call forth by the emergencies created by the recent i fluenza epidemic. The municipalities were utter unable to properly cope with this visitation. It w often impossible to get doctors, nurses, and ev nourishment, with the most elementary care, many stricken households. This should not be lowed to happen again. A proper organization health forces is needed to prevent the repetition such a calamity.

One important health problem in every locality the difficulty of getting good home nursing in ca of illness on the part of the poor and those in mo erate circumstances. While some localities ha good district nursing, on a charitable or semi-cha itable basis, something more is required by mul tudes of self-respecting people who are not in class for charity. Some development of the nursi profession that will train a large number of wom as practical nurses, or nurse's aids, is urgently quired. The hospitals should take up this importa question. It has been estimated that only abo one family in ten has a yearly income of over $1,2(and the average wage earner gets much less. T high cost of sickness is an urgent problem to m titudes of the best people in every community. The are not the ones who are proper subjects for t free wards of private hospitals or the cold char of municipal institutions. It sometimes seems as

modern medical attention can only function best with the millionaire or the pauper. We need a different organization of medical attention and nursing, even at the risk of socialization, to meet the actual needs of the day. This is a question for the people, organized in a Community Council, to approach at once.

In Russia, the people, through their cooperative societies and the Zemstvos, employ physicians and conduct hospitals and clinics as cooperative enterprises. The great sickness societies and "Krankenkassen" of Middle Europe are such cooperative institutions. In Continental Europe and Great Britain the cooperative societies are promoting health agencies with noteworthy success. Here we discover the lines of convergence of the scientific and economic aspects of health conservation. Before the war, when the cooperative societies of Belgium, through their economic administration, secured pure milk for babies, sent children on vacations from the city to the country, provided six weeks' rest for parturient women, secured sick benefits and unemployment pensions for workers, and were doing things for the protection and promotion of health, they rivaled the best that the competitive practice of medicine is able to accomplish.

A fundamental principle of cooperation in agencies to conserve health is shown by the sickness insurance societies. In Europe, this movement now embraces fully one-third of the population. We have a few expressions of the distinctly medical side in this country, in the sickness insurance societies and in the cooperative dispensaries conducted now in some of our colleges by the student body. The development of agencies for promoting the health of the people, if carried out on the cooperative principle, will represent the application of the Socialist ideal, stripped of its bureaucratic complications and made creative and free.

There should also be a close touch maintained with all the municipal departments, especially the Board of Health. This would prove of mutual advantage both to officials and people. It would tend to prevent, on the one hand, the dry, bureaucratic methods that sometimes prevail, and, on the other, undue criticism due to a misunderstanding of the problems and difficulties that frequently concern the public official. An effort must be made to secure unified action by the Health Department, hospitals, nurses, and practitioners—such action as would increase the medical output and provide the framework within which the popular health work can be organized. Questions here raised are of universal interest, and could immediately be turned into a sustaining motive for cooperative action in every neighborhood. While people may disagree on all possible questions, social and religious, there is unanimous harmony as to the desirability of good health, both individual and public.

In this connection it will be of interest to call attention to a most interesting social experiment in Cincinnati, Ohio. A city block was here taken as a unit of social effort on the part of the people themselves. Among other accomplishments, a complete and successful program of public health administration has been worked out, with a resulting decrease in local morbidity and mortality.

The great war of saving the world for democracy has been won. What will be the meaning and fruits of this victory? After democracy has been saved for the world at such bloody cost we must see to it that it is conserved and practised. Many years ago Carlyle said that the world's being saved will not save us nor the world's being lost destroy us. A new world condition will not be of benefit unless we mean to profit by it. Each citizen must partly take upon himself the duty of regulating individual and public life according to the best methods. Every community or State usually gets as good government as it is fit for and deserves. In a democracy we must work out our own salvation or lose our civic souls.

There is one great influence which war brings as its principal and only beneficial by-product. It is the enthusiasm, loyalty, unselfishness, and bravery invoked by the soldier's active life. Among the people, also, there is a sort of exaltation and forgetfulness of personal interests that go with the will to win in a righteous cause. How can this splendid enthusiasm be conserved and deflected into civic life, with all its difficulties and problems? Here is an opportunity for Community Councils to try and find some solution of this problem. Perhaps it will lie in trying to adapt some of the forms and spirit of military organization to civil life. The Salvation Army is an example of what may be accomplished by following this method. We have had a home army of defense. Why not try and organize a sort of civilian army for civic service at home? An army stands for discipline and service, and these are just the elements needed in the civil life of a democracy. We might be able to let the health requirements of the community lead the way in this regard, as the question is so fundamental. Each Community Council might institute a local army to fight disease in its district. Doctors and nurses could first be enrolled and then types of service found for volunteers. While this army will be an organization of the people themselves, it could have ranking officers, as titles of some sort seem to help in collective work. Many physicians have no hospital or dispensary positions, and they could first be utilized in the building up of the army. Besides the honor, such home service would be a proper means of bringing the physician to the notice of the community. Regular campaigns could be inaugurated against many common preventable diseases and the interest thus conserved. It would add one more, and perhaps the most useful form of a drive, to the many that have preceded it. The word "drive" seems to have touched the popular imagination, and hence would have a place in the work. The children could be collected into a junior health army, and thus do their share, at the same time becoming educated in the process.

One day last fall I happened to pass an armory, and looking through the open door saw a large company of young women marching and countermarching and being drilled in military maneuvers. They wore smart uniforms, and showed the effect of constant discipline. The thought occurred to me that while many women had shown splendid service and heroism in the war, none of them had been sent to the battle line as actual combatants, where quick command must be instantly understood and obeyed. At that very time, within a short distance of the place, there were hospitals and neighborhoods with an epidemic of influenza and pneumonia, where the

lack of nurses and helpers was meaning needless suffering, and even death, to not a few. I felt like taking over the command of that little army and marching it out of the armory down to the tenements and into some hospitals where suffering and death were as rampant as on the real battlefield.

Let us try and inaugurate what William James, with prophetic note, wrote in that memorable essay, "The Moral Equivalent of War." He recognized that the popular imagination is touched by the courage, audacity, and heroism of war. "We must make new energies and hardihoods continue the manliness to which the military mind so faithfully clings. Martial virtues must be the enduring cement; intrepidity, contempt of softness, surrender of private interest, obedience to command, must still remain the rock on which States are built." He recommends instead of military conscription a conscription of the whole youthful population to form for a certain number of years a part of the army enlisted against dangers inherent in nature and work. The military ideals of hardihood and discipline could thus be wrought into the growing fiber of the people. "To coal and iron mines, to freight trains, to fishing fleets in December, to dish washing, clothes washing, and window washing, to road building and tunnel making, to foundries and stokeholes, and to the frames of skyscrapers, would our gilded youths be drafted off, according to their choice, to get the childishness knocked out of them, and to come back into society with healthier sympathies and soberer ideas." While thus far war has been the only force that can discipline a whole community, an equivalent discipline must be organized, and this great thinker believes it can be done.

Certainly the future conditions facing democracy call for both courage and vision. Social and physiological inequality, the labor overturn, the slums of city and country, needless disease and death, and many other problems, require heroic qualities of mind and heart if success is to be obtained.

In the great world movements of the day democracy is rapidly coming to its own, at least as far as outward form is concerned. Let us see to it that the inward substance as well as the outward form is there. Otherwise, disappointment and disillusion await the tired toilers of the world. A government of the people, by the people, and for the people must function by the real and actual operation of the people themselves. Autocracy has failed—let true democracy now be tried. Mistakes will be made and false directions sometimes taken, but in the end will be corrected. The best educators are trial and experience. We cannot correct our mistakes, but we can let our mistakes correct us. The inauguration of Community Councils opens up a new and promising vista for the operation of real democracy.

51 West 51st Street.

Professor Sahli on the Causes of Influenza.—Sahli denies that the organisms commonly found in grippe are the causes only of secondary lesions. He would see a symbiosis more or less accidental between the pneumococcus, streptococcus, *Micrococcus catarrhalis*, Pfeiffer's bacillus, etc. All have been recovered from the nasopharynx and the depths of the lungs. The last named organism is known to give the best cultures when it is associated with the others quoted.—*La Presse Médicale.*

INFLUENZA IN A TUBERCULOSIS SANATORIUM.*

By ALFRED MEYER, M.D.,

NEW YORK.

On October 6, 1918, soon after the outbreak of the epidemic of influenza in New York City, and 3 days after the probable outbreak of the disease in the village of Bedford Hills, it was decided to establish a quarantine at the Bedford Hills Sanatorium of the Montefiore Home.

As many of you know, this institution is situated in Westchester County about forty miles from this city on a hill overlooking the village of Bedford Hills, distant about one-quarter of a mile. The institution is exclusively for the care of cases of pulmonary tuberculosis from the Greater City of New York. The quarantine consisted in rescinding all the usual permits to the patients to visit the city and forbidding all visiting from the city on the part of relatives and friends. None of the nurses and housestaff absented themselves from the institution, and the only outsiders so far as known who made periodic visits were three physicians, a dentist, and the tradesmen who brought supplies. The mail-boy, who was an inmate of the institution, made two trips to the village each day, but did not have influenza. The average daily population of the institution was 274, of whom 213 were patients. Seven weeks went by full of their awful toll of illness and deaths through Westchester County and the nearby villages of Bedford Hills, Mt. Kisco and Katonah, and we constantly congratulated ourselves upon our freedom from infection. The question of raising the quarantine was repeatedly broached, but vetoed by me, for it was quite evident that, considering the size of our population, our safety had lain rather in the quarantine than in any natural immunity, but it was confidently predicted that if any case of influenza should accidentally arise we would have many cases and some deaths, and unfortunately this prediction proved only too true.

The first case appeared on November 26 in a male ambulatory patient with far advanced tuberculosis, in a ward containing thirty-four beds, and I have not been able to establish the source of his infection. Although this case was promptly isolated, three more cases appeared in the same ward in the next forty-eight hours. By December 9, fourteen days after the outbreak, there were a total of forty-three cases, and the last case appeared on December 22. The total then was fifty-four, which represented almost 20 per cent. of the entire population of the institution. Two of the cases were non-tuberculous employees, a member of the house staff and the bookkeeper. There were six deaths, three male and three female—a mortality of a little over 11 per cent. Let me give you a few details of the fatal cases:

The first was that of a male drug clerk, twenty years old, who was suffering from a combination of exophthalmic goitre, a moderately advanced tuberculosis, though not bacteriologically proven, and with negative Wassermann and tubercle complement fixation tests, who died of a double pneumonia on the sixth day. There had been 19 nega-

*Read at a meeting of the Section on Medicine of the New York Academy of Medicine, February 18, 1919.

tive sputa, of which three had been antiformin.

The second death was a male cloak-maker, aged forty years, with positive sputum and extensive bilateral lesions. He had been febrile from his admission in June until early in November, which confined him to bed with temperatures between 100° and 101°. He had lost thirteen pounds in weight before his influenza. The temperature suddenly rose to 104° with marked prostation, a rapidly developing dyspnea and cyanosis, and death on the third day. This case was the one with the most rapidly fatal issue.

The third death was that of a young woman of twenty-one, a clerk, who had only been in the institution four weeks with a bilateral lesion, including a cavity in the left upper lobe. In spite of the extent of her disease, she had been afebrile and gained five pounds in this short period. She suddenly became acutely ill with temperatures ranging between 103° and 104° and died in six days with scattered areas of bronchopneumonia.

The fourth death was of special interest because it occurred in a young girl of twenty-four, in whom I had established a fairly complete left artificial pneumothorax at Mt. Sinai Hospital some months before, subsequent refills having been done in three weekly periods at Bedford. She had been there all told five and one-half months, had lost her fever, and gained fifteen pounds in weight, and was an ambulant patient. Soon after the onset of her influenza symptoms her temperature rose to 105°, and she developed a pneumonia of the right upper and lower lobes and died in nine days. She menstruated during her illness, and I am mentioning this fact because I am wondering whether it was in part responsible for her hyperpyrexia. I wish to leave this an open question, but from observations made in many other women in the city I am inclined to believe that menstruation tends to make the fever run higher; in fact a large proportion of the cases that I saw elsewhere with temperatures of 105°, 106°, and over were in menstruating women. Another question of interest arises in this case. Would it have been advisable to let the nitrogen out of her left chest even if siphonage had been necessary to withdraw it, and would the left lung have expanded, and would the pregnosis of her right pneumonia been improved? The left lung had been collapsed for a period of about seven months with a final pressure that was usually around zero, and the last inflation with 700 c.c. of nitrogen had been made three days before her influenza began.

The fifth death was that of a young woman of twenty-one years with a bilateral apical tuberculosis. She had been in the institution seven weeks, had been afebrile, and had put on ten pounds. The right lower lobe pneumonia never resolved up to the time of the patient's death two months later, which was the longest duration of any of the six fatal cases.

The last death was of a young clerk of seventeen years, with a cavity in his right upper lobe, who had been in the institution over seven months, had become afebrile, and had gained four pounds. At the end of the first week of his influenza his temperature dropped to normal, remained there three days, just as it does sometimes in the non-tuberculous, portending convalescence, then rose again to 103° and 104°, continuing thus with slight variations until his death on the fifty-sixth day of his acute illness. There were no autopsies on any of these six cases.

It is of interest to note that over 98 per cent. of the cases were under forty years of age, although only 84 per cent. of the population was comprised within this age limit, or, to put it differently, there were less than 2 per cent. of cases over forty years of age, although that age period was entitled to 16 per cent. of the morbidity, showing that there was a greater age predisposition in patients under forty years.

The clinical picture did not differ essentially from the disease as we see it in the non-tuberculous, and it is too early now to say what effect the inter-current illness has had on the tuberculosis, but in at least seven of the cases there are indications of renewed activity of the tuberculosis and an extension of the original process. The average duration of illness in 46 of the cases that recovered was about six days.

It is to be regretted that many other sanatoria of the country have had a similar experience, with an effective quarantine for varying periods of time, only to be disappointed in the end by an outbreak of the epidemic. This happened at three State sanatoria in Massachusetts—Rutland, Westfield, and Lakeville. At Westfield 75 children out of 150 became ill and 4 died. Later there were 8 deaths out of 16 adults who became ill.

Dr. Wilson, Director of Hospitals of the New York City Health Department, reports in a personal communication to me that they were free of the disease at Otisville until they permitted 45 or 50 of their men to go to New York during the Christmas holidays, 2 of whom returned in the active febrile stage. Subsequently 50 cases came down. Of these 50 cases, 5 died. Not a single case developed in the women's unit.

At the Trudeau Sanatorium quarantine was effective until February 8, when they had their first case. I cannot say how many secondary cases developed.

Dr. Palmer also, in a personal communication to me, reports that at the Springfield Open Air Colony in Illinois for thirty-five adults the quarantine was effective for two months, when a new patient brought in the disease, from which 15 cases developed with 3 deaths.

At the Naperville Sanatorium, also in Illinois, quarantine was primarily effective, but ultimately there was an outbreak with 2 deaths out of a population of about 150 patients and employees.

The only medical institution of which I have knowledge which up to date has been perfectly successful in keeping out the disease is the hospital in San Francisco in charge of the Public Health and Marine Hospital Service, but this instituition is situated on an island. Dr. Heise reports that a space on the wharf was roped off, within which the supplies were dumped from the boats, and not until the boats with their crews had departed were the shore employees allowed to collect the supplies. Thus all personal contact with San Francisco and the rest of the world was eliminated and with it the introduction of the disease.

28 East Seventy-fifth Street.

NOTES ON A MONTH OF INFLUENZA AT A BASE HOSPITAL IN FRANCE.

By S. BRADBURY and E. B. KRUMBHAAR, Capts., M. C., U. S. A.,

16 (Phila. U. S. A.) Genl. Hosp. B. E. F.

Statistical.—Between October 12 and November 12 there were admitted to No. 16 (Philadelphia, U. S. A.) General Hospital 533 cases of influenza, representing the height of the epidemic in this locality. Of this number, 444, or 83.3 per cent., ran an uncomplicated course and recovered in from four to eight days (though their stay in hospital was naturally longer). Ninety, or 16.7 per cent., developed pneumonia, and of these, 45, or exactly 50 per cent., died (8.3 per cent. of the total number). Death occurred from 5 to 17 days after the onset (average duration of 10 days). While these figures include some convoys of convalescent patients, they also include many cases in which pneumonia had developed before admission to this hospital. It is of interest that although the influenza epidemic last spring was much milder in character in this region, 3 deaths (confirmed by autopsy) occurred in this hospital during June and July.

Clinical.—The disease has been of sudden onset, the usual complaints being extreme prostration, severe frontal headache (often described as being in or behind the eyeballs), general aches and pains, and often chilly sensations. Constipation is the rule, though vomiting and diarrhea are occasional complaints. In physical examinations of these early cases often the only evidence of illness is fever and a coated tongue. This is usually accompanied by a noticeably slow pulse and normal respiration rate. Most patients have a severe non-productive cough and frequently epistaxis. Many cases have cyanosis from the onset, even those in which no pneumonia appears. Others complain of pain in the upper abdomen, which may be muscular or pleural.

Complications of minor degree have been frontal sinusitis, otitis media, inflammation of the antrum, and severe laryngitis, rendering the patient voiceless and in a few instances making deglutition painful. In simple cases the fever subsides in 4 to 7 days. Relapse, or recurrence of the fever and all symptoms, has occurred frequently, and is usually milder than the original infection.

The most serious complication, pneumonia, may begin during the fever or in the 2 or 3 days after its cessation. In the severe type, its onset is indicated by increased temperature, cyanosis, rapid pulse and respiration, and a more severe cough, productive of purulent sputum. It is usually nummular, sometimes extremely tenacious, like that of lobar pneumonia, and in some instances very abundant, amounting to 300 to 400 c.c. in 24 hours. Rarely it is blood tinged, and a few men with pneumonia have had small, frothy hemorrhages shortly before death. Examination of the chest at the onset shows no definite dullness, but suppression of breath sounds at one or both bases, with a few very fine crepitant râles. Later, signs of consolidation (dullness and bronchial breathing) are found, but they appear and disappear from day to day in different parts of each lung. In early fatal cases the cyanosis rapidly increases, delirium supervenes, and in 36 to 60 hours death occurs. In late fatal cases the cyanosis continues, signs may become definite in one area, with changeable signs throughout the remainder of the lungs, the patient wastes rapidly, cough is severe, with abundant sputum, delirium is nearly constant, and after 7 to 14 days the patient collapses, breaking into a drenching sweat, with a weak, rapid pulse, which fails to respond to any stimulation. Several men have appeared to be progressing favorably when they complained of sudden pain over one or the other lung, and shortly after collapsed, and died in 5 or 6 hours.

Complications of the pneumonia have been frequent and universally fatal. Three men developed jaundice. In 2 of these 3 there was an urticarial rash of about 24 hours' duration, occurring several days before death, and one of these patients had septic emboli in fingers of the right hand, on the outer side of the thigh, and either an iritis or panophthalmia of the left eye, with *Streptococcus hemolyticus* in the blood. There was 1 case of pneumococcic meningitis, and in one man who had severe aortic regurgitation fresh vegetations were found on the aortic leaflets post mortem.

In the non-fatal cases the temperature falls slowly to normal, but often the patient is very ill, with rapid, weak pulse, rapid respiration and cyanosis for 2 to 5 days after all fever has disappeared. Convalescence is extremely tedious, the men being weak, emaciated, and with cough, expectoration and rales in the lungs continuing for 2 to 3 weeks. In one case there still persist râles and rough breathing at one base, and it is now 4 weeks since the severest point of the disease was passed.

Pathological.—Autopsies were performed on 28 cases. All of these showed pneumonia and acute fibrinous pleurisy to a greater or less extent, and 11 showed in addition extensive multiple streptococcic abscesses of one or more lobes. Two of these had further progressed to pyemia with abscesses in liver, spleen, and kidneys, and streptococci isolated from the blood stream ante mortem. In 8 cases the lung abscesses were associated with a shaggy streptococcic pleurisy, usually with a turbid effusion (empyema). In the other 3 the subpleural abscesses apparently ready to burst indicated the intrapulmonary origin of the pleurisy.

Of the pneumonic lungs not complicated by abscesses, a few showed a typical focal peribronchial bronchopneumonia, usually with pus in the central bronchiole, and 2 ordinary lobar pneumonia (red and gray hepatization). The majority, however, were of an intermediate type that has not hitherto been encountered by the writers. In these cases were found large portions of a lobe, of a homogeneous, firm, heavy, wet, red character, with a peculiar boggy, meaty appearance. It was only after scraping off considerable blood and serum that widespread consolidation became apparent, and the color was seen to vary from dark red to grayish pink. Some of these tissues floated low in water, others sank. In 4 of these cases the scraped fluid had a semipurulent tinge and gave somewhat the impression of a resolving lobar pneumonia. In some cases of this type (apparently those of longer duration) the homogeneity of the lung tissue was less marked. The translucent, semisolid, edematous tissue was then seen to be divided apparently regardless of

the lung structure by well defined moist, raised, gray, granular belts. These occasionally appeared as septa penetrating vertically from the pleural surface. Histologically, leucocytes are not very prominent in the alveoli of such lungs. Many alveoli are packed with red blood cells, almost obliterating the lung structure; others contain a mixture of red blood cells, fibrin, serous fluid, and nucleated cells in various proportions. Of the latter, small round cells and plasma cells usually predominate over the polymorphonuclears and the pigment-bearing, wandering cells. Sections from the paler and granular areas show polymorphonuclears predominating, with a picture resembling confluent bronchopneumonia. The incidence of the various types of pneumonia bore very little relation to the duration of the disease, abscesses being found in those dying as early as the 5th or as late as the 17th day and the intermediate form occurring as early as the 5th or as late as the 20th day. The spleen in 6 cases was but little changed from normal; in all the others it was slightly enlarged (up to 250 gms.), but with very prominent, enlarged Malpighian follicles and dark purple pulp. The other organs showed more or less cloudy swelling, with occasionally dark congested kidneys. In one case death was attributed to kidney insufficiency and dilatation of the heart, though bronchopneumonia was also present. The bone marrow was found hyperplastic, as in most acute infections. The trachea and bronchi of the earlier cases were congested, covered with a glairy, often bloody, fluid. Those of the later cases were but little changed from normal.

Bacteriology.—Post-mortem smears and blood agar cultures from the lungs were carried out in 18 cases. In only 3 were organisms resembling the Pfeiffer bacillus encountered and 2 of these died early. In all cases *Streptococcus hemolyticus*, pneumococcus, and a sprinkling of other cocci were found, depending on the part of the lung examined and the duration of the case. In the earlier cases pneumococci predominated and large clumps of these organisms could be identified histologically in the alveoli. In the consolidated areas and the pleural exudate pneumococci and hemolytic streptococci were often associated, the former usually predominating, with other cocci occasionally present. The abscesses and septic pleural fluid, however, invariably contained a majority of hemolytic streptococci, though pneumococci were also present. It, therefore, seems as if the Pfeiffer bacillus, if ever present, had usually disappeared before death supervened, and that pneumococci were chiefly responsible for the consolidation, and streptococci for the suppuration, though it is not apparent whether or not the lung must pass through the stage of consolidation before suppurating. Time did not permit the isolation of the types of pneumococci, or further subdivision of streptococci; the diagnosis of these and other organisms was made by their morphology and growth on blood agar only.

Vaccine Therapy.—A tardy attempt was made to protect those who had already developed influenza from pulmonary complications by giving a polyvalent vaccine. This was prepared from cultures from the lungs of three fatal cases, and contained approximately 40 per cent. each of streptococcus hemolyticus and pneumococcus, and the remaining 20 per cent. of staphylococci and an unidentified Gram negative bacillus. It was given in doses of 200 to 300 million, to febrile cases only (*i.e.* still possible contractors of pulmonary complications). Of 33 thus treated, none developed bronchopneumonia and the medical officers in charge gained the impression that (possibly due to the non-specific effect of foreign protein) a favorable influence was exerted on the course of the influenza. In 6 cases in which pneumonia was already present the vaccine was given at the request of the medical officers without any great expectation of doing good. The fact that 4 out of the 6 died indicates (as would be expected) that such vaccines are too late when given after pneumonia has already begun. Convoys of convalescent cases only, after the cessation of hostilities, prevented this vaccine from being employed on larger numbers.

Clinical Pathology.—Leucocyte counts were made on 20 patients, 10 of whom had pneumonia at the time. Leucocytosis was present in 6, all of whom had pneumonia or other complications. A leucopenia (2,600 to 5,400) occurred in 7 cases, 5 of which had bronchopneumonia at the time. Differential counts in 13 of the 20 gave inconstant results, but apparently the chief changes were due to variations in the polymorphonuclears. In one septicemic case with a leucopenia of 4,400 per cubic millimeter, premyelocytes and Turck irritation cells were common. Three of the 7 leucopenia cases and 4 of those with leucocytosis died, but the writers feel that a larger series would confirm the view that leucocytosis is a good omen in the presence of influenza complications. The urine of severe cases usually showed a cloud of albumin and many hyaline and granular casts. In all the mild and many of the severe cases routine urine examinations were normal.

Summary.—1. During one month, of 533 cases of influenza admitted to a base hospital, 83.3 per cent. ran an uncomplicated course, and 16.7 per cent. developed pneumonia. Of the latter one-half died, two with pyemia, one with acute endocarditis and one with meningitis, in addition to the pneumonia.

2. The uncomplicated cases ran a fairly typical course. The frequency and high mortality of pulmonary complications was striking, also the tendency to hemorrhages, from lungs and nose and probably in 2 cases beneath the skin.

3. In 28 autopsies all showed a more or less extensive acute pleurisy and pneumonia (rarely a typical lobar or focal bronchopneumonia). Eleven, in addition, exhibited multiple streptococcic abscesses of one or more lobes, and 8 of these a septic pleurisy (empyema).

4. Pneumococci predominated in the earlier consolidations, and *Bacillus Pfeiffer* was found only 3 times in the lungs post mortem. Hemolytic streptococci predominated in the abscesses, but both forms, as well as staphylococci and other occasional organisms, were found in most cases of the consolidated lungs.

5. Leucopenia was present in 7 of 20 cases, though 5 had pneumonia at the time. Leucocytosis occurred in 6 others, all of whom had complications at the time.

6. Polyvalent vaccines (intended to protect against pulmonary complications) were given to 33 febrile cases. None of these developed pneumonia. Vac-

cines given to a few cases in which pneumonia had developed were of no benefit.

Note.—For a comprehensive review of the work on the present pandemic, the reader is referred to the October number of the "Medical Supplement" (compiled by the Medical Research Committee of Great Britain), page 354.

DISORDERS OF THE SEXUAL FUNCTION, MASTURBATION, WITHDRAWAL, IMPOTENCE, ETC., IN RELATION TO CONDITIONS IN THE POSTERIOR URETHRA.*

By MAX HUHNER, M.D.,

NEW YORK.

CHIEF OF CLINIC, GENITOURINARY DEPARTMENT, MOUNT SINAI HOSPITAL DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE; MEMBER, AMERICAN UROLOGICAL ASSOCIATION, ETC.

THE posterior urethra is that portion between the anterior layer of the triangular ligament and the bladder. It is about two inches in length and includes both the membranous and prostatic urethra. The prostatic portion is its widest and most dilatable portion. The canal is somewhat spindle-shaped, being wider in the middle than at either extremity. It extends from the bladder to the membranous urethra, and runs vertically through the prostate gland.

Upon the posterior wall of the prostatic urethra is situated that very important structure, the verumontanum. This is about 12 mm. in length and about 3 mm. in height, although these measurements vary greatly in different individuals.

I wish right here to call attention to a fallacy which has been copied from one textbook into another even to quite recent times. It has been asserted that the function of the verumontanum is to close the pathway toward the bladder during coitus, so that semen shall be prevented from going into the bladder. This theory is absolutely false for many reasons which time does not permit me to enumerate.

The most modern theory as to the function of the verumontanum is that it affords a crest upon which the ejaculatory ducts may open. The prostatic ducts open on the floor of the urethra, and converge toward the verumontanum. During ejaculation, therefore, this arrangement brings about a complete intermingling of the thick gelatinous semen and the thin prostatic fluid from the ducts, thus causing a homogeneous fluid, which enhances and preserves the vitality of the spermatozoa.

This then, in brief, is the prostatic portion of the urethra. Although only a little over an inch in length, it is one of the most interesting and important parts of the male anatomy considered from the point of view of sexologist, urologist, neurologist, and general practitioner. In this comparatively small portion of the male anatomy are found structures, the disease or infection of which may cause more annoyance, more misery, and more serious consequences than any other portion of equal size, with the possible exception of certain vital areas in the brain.

*Paper read at a meeting of The Yorkville Medical Society, April, 1918.

It is out of the province of this paper to discuss the consequences of gonorrheal infection of this portion of the urethra. The urologic importance of the posterior urethra has sufficiently often been emphasized, but its sexual importance is not so well known.

It may be hard to realize, for one not experienced in posterior urethroscopy, especially in the urethroscopic picture of the so-called sexual neurasthenic, what tremendous symptomatic effects may result from apparently slight pathological changes. Those who expect to find *gross* pathological lesions in the posterior urethra in such markedly perverted conditions as impotence, masturbation, and the like, will often be doomed to great disappointment. After much experience they will finally realize that a slight congestion in the region of the verumontanum, a congestion which is often overlooked or considered trivial by the inexperienced, may be, and in fact very often is, the cause of the gravest symptomatic consequences. As a matter of fact, often the most gross pathological lesions in the posterior urethra, which are sometimes discovered during a routine examination, may not cause any disturbance whatsoever, either psychic or functional.

I wish also to correct another fallacy which seems to dominate the minds of many clinicians, and notably many genitourinary specialists. There seems to be a widespread opinion that many of the lesions found in the posterior urethra are the result of previous gonorrheal infection, and that the majority of cases of impotence are likewise the result of such infection. This is far from the true state of affairs. The reason for this mistaken notion by many genitourinary men is easy to understand. Almost all of those who have written upon the subject have gathered their material and experience from their *genitourinary* classes. They look into the posterior urethra, find certain pathological conditions therein, and, because in almost every case they obtain a history of one or more gonorrheal infections, conclude therefore that the gonorrhea must be the cause of the pathological conditions present and of the symptoms complained or by the patient.

It has been my particular good fortune, however, to have been associated for a period of several years with the neurological clinic of Dr. Abrahamson at the Mount Sinai Hospital Dispensary, where I examined the posterior urethra in every case of sexual disorder, as well as in many cases of nervous conditions, believed by Dr. Abrahamson to have a sexual basis.

The vast majority of these patients had never been infected with gonorrhea. Most of them were the old-time Jews of Russia and Austria, who, according to the customs of those countries, had married very early, and thus escaped the temptations of illicit coitus and its consequences. I was at first surprised to find in so many of these cases many of the pathological conditions which were generally attributed to gonorrheal infection. But more experience, after very many examinations, has convinced me that such lesions are not necessarily or generally due to gonorrhea at all, but to other conditions to be later described. The same fact is true of impotence. The vast majority of

my cases of impotence, both in dispensary and private practice, did not have a gonorrheal etiology. I do not of course mean to infer that gonorrhea does not leave its mark in the posterior urethra, or that impotence may not be caused by gonorrhea. I only mean to emphasize that it is only the smallest percentage of cases of gonorrhea that are followed by impotence. I almost wish it were otherwise. If every gonorrhea were followed, for a while at least by impotence, it would not only greatly limit the spread of the infection, but would be one of the mightiest deterrents to the performance of illicit coitus.

Let us now consider the relationship of the posterior urethra to some of the more common disorders of the sexual function. Let me call your attention to perhaps the most widespread disorder, namely masturbation.

The pathology of this condition is in brief as follows: Through some accident, due perhaps to a tight prepuce, to smegma or other local condition, the child manipulates its penis. This first manipulation may be done purely accidentally without any thought of sexual pleasure, or it may have been taught to the child by older boys. Whatever the cause, this manipulation of the penis sends an impulse to its brain, which, as in ordinary coitus, sends an impulse to the muscles of erection, and also determines an increased blood supply to the prostatic urethra as well as to other portions of the genital tract. So far the condition is like ordinary coitus. But this act frequently repeated leads to a permanent hyperemia of the prostatic urethra, so that impulses from here are being constantly sent to the brain, which again in response sends continuous sexual impulses to the prostatic urethra and adjacent sexual organs, thus still further increasing their congestion. A vicious circle is thus formed. Later on there is formed such an intense hyperemia and hyperesthesia of all these parts, that the patient *must* masturbate, just as one afflicted with scabies must scratch. The difference between masturbation and normal coitus is, in the first place, that it is initiated at, or even before puberty, when the sexual apparatus is still in an imperfect or developmental state, when the sexual centers appertaining to this function are also being developed, are immature and more irritable, and in short when the whole body is undergoing profound chemical, physical, and psychological changes; and, in the second place, that the act is repeated much more frequently than normal coitus could be. Even if a normal adult, with fully developed sexual organs, were to attempt coitus as often as some of these patients masturbate, the result would also be disastrous. But when we consider that in the masturbator, the act is so often accomplished with immature and undeveloped organs, with an overirritable brain, and at a time when all the energy is needed for bodily development, not only in this particular field, but in every function of the body, we can easily understand why the results are so profound.

Such then, very briefly, is the pathology of the confirmed masturbator. I say "confirmed" on purpose, because I do not wish to give the impression that every masturbator goes on to the formation of this pathology. Far from it. Many stop the habit very early before the vicious circle has been formed and before there has been produced much congestion and much hyperesthesia in the deep urethra.

It would take me too far afield to go more deeply into the pathology of this condition in its various forms, but I would like to refer briefly to one very interesting feature of it.

There has been for a long time much discussion about the influence of mind over matter, and more particularly, if it is possible to cause *organic* changes in the body, purely by the unaided influence of the brain. I believe that the discussion has been definitely settled, but the subject of psychic masturbation affords a strikingly affirmative proof of the fact that the unaided brain can produce definite pathological organic changes. In psychic masturbation there is no manipulation of the penis or other sexual organs, but the mind calls up lewd and sexual images, and through these alone erection and orgasm are produced just as in manual masturbation. Now, if this process is continued for a long time, there is produced the same organic pathological condition in the prostatic urethra, as in manual masturbation. The pathological condition can be easily seen through the urethroscope, and the picture is absolutely the same, whether produced by manual or psychic masturbation.

I cannot stop here to give a detailed account of the symptoms and treatment of masturbation.* Briefly, however, the confirmed masturbator presents a symptom complex that deserves our greatest sympathy. While the general nervous symptoms have at times been grossly exaggerated by quacks, still they do exist, and are at times very severe. The entire psyche of the patient is often affected, so that he loses all ambition, and what work or study he is compelled to do, he does under a tremendous nervous strain, and at the expense of an enormous amount of nerve energy.

The treatment, in brief, is to get rid of the hyperemia of the prostatic urethra, by silver nitrate instillations, and to reduce the prostatic congestion by massage. The results are truly gratifying, and it is one of the most pleasant experiences of the physician to see a new psychic and physical being actually produced out of a pitiable nervous wreck; and all this is accomplished by merely getting the prostate and posterior urethra into a normal condition. As before said, it is hard for those without experience to realize how a simple congestion in the posterior urethra and prostate can be the cause of such marked physical and psychic symptoms, and how the relief of such congestion can have such happy results.

Let us take another sexual disorder, namely coitus interruptus or withdrawal. I am sorry that, in order to make this paper comply with the time limit, I have had to cut out the detailed description of the pathology of withdrawal. I can only say, instead, that as a result of the continued indulgence in this habit, there results an intense congestion of the posterior urethra accompanied as a rule by swelling of the verumontanum. There is also at

*A complete description of the pathology, symptoms and treatment of masturbation will be found in my book, "A Practical Treatise on Disorders of the Sexual Function in the Male and Female," F. A. Davis Co., Philadelphia.

first a hyperirritability of the erection and ejaculatory centers in the spinal cord, so that, at this stage, ejaculation takes place at the very commencement of coitus, often before the penis has entered the vagina. Later there occurs a complete exhaustion of these centers, so that they refuse to transmit impulses to the genitals, and thus we get the clinical picture of complete impotence.

As regards the symptoms following withdrawal, they are so various and so numerous that they embrace almost every medical specialty from neurology to orthopedics. Under the title "Some Unusual Forms of Sexual Neuroses," I reported several years ago some interesting and unusual cases, such as symptomatic sciatica, various anesthesias, neuralgic pains in different organs of the body, all due to the pathological conditions induced by this pernicious practice. Here again, it is hard to realize, were we not confronted with the most scientific clinical proof, how a slight or severe congestion in the posterior urethra, in combination with congestions in the adjacent sexual organs, can call forth such a variety of symptoms. The sexual results of this practice are very often rapid and premature ejaculation and finally complete impotence.

It would take me far beyond my time limit even to touch on the misery to both husband and wife from these latter sexual symptoms alone. Even without complete impotence, the nervous strain on the wife is exceedingly great. At the commencement of coitus, she is just about sexually aroused, but, on account of the rapid or premature ejaculation of the husband, she is left in an unsatisfied nervous state. Frigidity, unfaithfulness, and divorce are not infrequently some of the dire results, and all due to simple pathological and, in most cases, curable conditions.

As regards the treatment of this condition and the resulting impotence, it will be impossible to go into much detail and only the essential points will be given. It is not my intention to-night to give a description of my present method of treating impotence, as it would take up too much time, and I would refer you to my book previously mentioned. But whatever is done, the first thing necessary is to get the urethra into a normal condition, that is, to get rid of the congestion and inflammation. There are very many physicians who, when a patient presents himself suffering from impotence, will at once resort to stimulants, electricity, etc., etc., with the idea of improving the erections. There are some also who consider the entire subject of impotence and its treatment as something mysterious. Nothing could be farther from the truth than both these latter statements in the ordinary cases of impotence. There is nothing mysterious or out of the ordinary about the treatment of impotence, but it is exactly what would be done for any other organ of the body if similarly affected. The first principle is to restore the hyperemic mucous membrane to its normal condition, and also to give the tired and exhausted sexual centers a chance to recuperate. Absolute sexual rest is essential. Not only abstaining from coitus, but also abstaining from "spooning," kissing, or anything that might excite these centers. At all events coitus must not be indulged in. Surely if a patient had a swollen elbow, with its limitation of motion, the surgeon would at once put the elbow at rest by various appliances till the inflammation was gone, and then only would he employ passive motion, massage etc. But during the height of the inflammation, if the patient were to jerk his elbow in the same manner as one of these impotents tries to manipulate his penis in his attempt at coitus, the elbow would not get well either.

Nature tries in her own way to help the patient to accomplish these results. She often takes away the desire for coitus, she makes the man more or less impotent, so that he cannot have erection and ejaculation, so as to give the parts a chance to become normal. The impotence is the best thing for the patient under these circumstances. But it is the height of folly to thwart nature, and give so-called sexual stimulants, and try to make the exhausted centers, and the inflamed mucous membrane, and the tired muscles work, just when rest is so greatly needed. After the inflammation has subsided, and the centers have been rested, then stimulants and moderate coitus may be indulged in.

There are other sexual neuroses which are in part dependent upon pathological conditions in the posterior urethra, but time will not permit me to go into them. It is very important to remember in this connection that the posterior urethra is but one of several organs which are affected in these conditions, and it is generally the disease of all of them together, which causes the symptom-complex, and, as in the case of other portions of the anatomy, we cannot take one organ out to the exclusion of the others in citing the blame for the symptoms.

There is but one point more in the pathology of the posterior urethra which I desire to emphasize. I have given a mere outline of the important part played by the posterior urethra in the causation of some of the sexual neuroses. I have shown the great amount of misery and unhappiness which may be caused by this small portion of the human anatomy if diseased. I will now briefly show how conditions therein may also be the determining of criminality in the individual. There has been much discussion whether crime in general should not be considered a disease rather than a defect in morals and ethics. In many cases, however, this has merely been a theory, and not susceptible of actual scientific proof, but in the class of cases briefly to be described, such proof has been demonstrated.

Take the case of an elderly gentleman of about 70, who has always led an exemplary life, and in whom the sexual appetite has long been extinguished. Suddenly the sexual libido is reawakened, but in a most perverted form. He takes sexual liberties with young children, and narrowly escapes landing in the criminal courts. His actions, in fact, make him legally a criminal. He consults a sexologist, and on examination, a very enlarged congested verumontanum is discovered surrounded by granulation tissue. A very simple procedure removes most of the verumontanum as well as the granulation tissue. He is at once restored to his normal equilibrium, and his pervert tendencies never return. He is thus restored from a criminal of the vilest type to a respectable citizen. Such cases have been reported. I have also had a young patient suffering from satyriasis who spent all the money he earned on prostitutes, and who told me

that he would have indulged in coitus several times a day, if he had the price. Every time he saw a female, he had an almost uncontrollable desire to have connection with her. He had all he could do to resist the inclination to commit rape on several occasions. In this patient also, an examination revealed an enormous swollen verumontanum filling up the entire prostatic urethra. Treatment brought the organ to a normal condition, and also cured his satyriasis, which would undoubtedly sooner or later have made a criminal of him, and a criminal of a class upon whom no sympathy is wasted, and who, even if he escapes death by lynching, receives certainly the most severe punishment for his crime. In a paper I recently published in *The Medical Times* under the title, "Is Rape Always a Crime?" I have gone more particularly into this subject from both a medical and medicolegal point of view. I do not wish to be understood as saying that all men with satyriasis or sexual perversion have a diseased prostatic urethra as an underlying cause. Far from it. It is most probable that in the case of the old gentleman with the perverted sexual feeling, as well as that of the young man with the satyriasis, there was present some cerebral or psychic underlying tendency; but as long as his sexual apparatus was in a normal condition, these criminal psychic perversions could be kept so far in the background and so under control as to lead to no serious consequences, but if, added to the pervert tendency, there is present a terrible irritation and sexual stimulation from the diseased prostatic urethra, this added irritation is enough to turn the tide, and make a criminal out of a normal person.

In conclusion I wish to state that this paper was not to be a paper on impotence, masturbation, or other sexual neuroses, but primarily a paper on the posterior urethra, and its relationship to the various neuroses and sexual perversions. It was therefore out of its province to discuss the importance of the other sexual parts, the prostate and seminal vesicles, as well as the importance of the brain and spinal cord upon the etiology of such neuroses. The paper, as just stated, was to be on the posterior urethra, and I believe I have shown that this little inch of human anatomy contains structures which if pathologically affected may be the cause of extreme misery, and produce the most far-reaching results and consequences.

320 Central Park West.

PNEUMONIA AT BASE HOSPITAL NO. 53, A. E. F.

BY MAJOR MAURICE L. GOODKIND, M.C., U.S.A.,
CHIEF OF THE MEDICAL SERVICE.

The intense concentration of large bodies of men provides suitable conditions for the development of infectious diseases, of which notably three types are to be considered: (1) Typhoid group: Typhoid, paratyphoid, colon. (2) Dysentery, amebic and bacillary. (3) The pneumonias.

Under the system at present in vogue, of general inoculation of all troops, the typhoid group, which in previous campaigns played so important a rôle in the augmentation of both the morbidity and mortality rate, is today practically a negligible factor, as, while occasionally met with, it is of comparatively infrequent occurrence.

Unfortunately, the same statement does not hold good in reference to dysenteric disorders, of which a very large number are encountered, despite the frequent and vigorous protests issued by the Chief Surgeon of the American Expeditionary Forces in regard to the precautions to be maintained concerning food and drink. The bacillary is the ordinary type occurring in the A. E. F., though recent epidemics of enteric disorders have appeared, associated with frequent stools, in which blood and mucus occur, with tenesmus, some febrile movement thew eakness, and in whose dejecta no organisms of the amebic or bacillary type could be found. It was therefore concluded that the exciting organism of this group was probably a filtrable parasite, which has not yet been identified.

The third member of this group is the one which has proved the most serious problem with which the medical personnel of the A. E. F. has been confronted. As in civil life, the pneumonias are a great menace and extract a high toll from the young and robust elements of our population, so in army life this has proven our most serious concern. In discussing pneumonia in civil life, as it refers to the ages with which we are concerned in the army, the mind reverts to the usual type met with, the croupous or lobar type; associating with the extremes of life, the very young and the very old, the lobular or bronchopneumonias, but this relationship of type to age is not maintained in our military experience, as there is a preponderance of the lobular type, which was very considerably in excess of the lobar form in our series of cases, and, from the perusal of the literature, I judge that this is a rather universal experience among the base hospitals of the A. E. F.

The important factor accounting for this fact is the general prevalence of measles and influenza. Another contributing cause, which we have not had to take into consideration previously, is the inhalation of deleterious gases. Contrary to the experience which we had in the camps in the United States during the season of 1917-1918, when measles prevailed so extensively and was a very frequent antecedent of bronchopneumonia, in our large series of patients at Base Hospital No. 53 this disease could not be regarded as responsible in a single instance. On the other hand, we had to contend with a new factor, which was accountable for many of the cases occurring here and which were generally of a fatal type, associated with a most marked dyspnea and cyanosis, a great tendency to the development of pulmonary edema, especially in the lethal forms, and due to the inhalation of deleterious gases, of which the mustard, chlorine, and phosgene were the ones commonly responsible.

After eliminating all other causes, influenza still remained as the most potent cause of our pneumonias. It was probably responsible for 90 per cent. of all our cases, and while occasionally associated with the lobar form, it was most frequently followed by the lobar or bronchopneumonic type, in the proportion of approximately one to ten.

A résumé of our lobar pneumonias demonstrates no radical departure from the disease as it occurs in civil life, its frank onset with chill and rusty

viscid sputum, increased leucocyte count, and definite physical signs rarely afforded difficulty in diagnosis. It was also, as a rule, of shorter duration and better prognostic outlook than the lobular form, which will now be taken up in greater detail.

Bronchopneumonia, which is occasionally designated as lobular or catarrhal (capillary bronchitis of the early writers), constituted fully 85 per cent. of the total number treated. The most frequent factor predisposing to its occurrence was influenza. Its onset was usually insidious, and it was frequently overlooked during the course of an influenzal attack because of the vagueness of the physical signs, which at the inception of the disease, consisted largely of the presence of subcrepitant rales, which were most profusely distributed over the bases, especially the right. Frequently some days elapsed before areas of dullness and bronchovesiculare breath sounds could be determined.

These physical signs occurred most often over the right lung and involved the lower lobe with especial frequency. Occasionally there was an agglutination of many adjacent lobules, which afforded definite physical signs of consolidation (marked dullness, pure bronchial breath sounds, bronchophony, pectoriloquy, and increased tactile and vocal fremitus), simulating the lobar form.

While the right lower lobe was the seat of predilection it was not infrequently associated with changes in the left base. At times all three lobes of the right lung were involved with no physical signs present in the left lung, thus presenting the picture of a unilateral bronchopneumonia, which observation was further confirmed by radioscopic examinations and occasionally at the autopsy.

In those patients suffering from influenza, when the physical signs were not sufficiently developed to justify the diagnosis of pneumonia, the probability of the disease existing was nevertheless entertained, when marked dyspnea and cyanosis were present out of all proportion to the physical signs, a persistence of the temperature over several days, the absence of marked throat, sinus, or ear pathology, a persistent spasmodic cough not unlike that occurring in pertussis, and with marked prostration. The last vestige of doubt regarding these potential pneumonias was removed on the appearance of a sanguineous-mucoid sputum, differing from the sputum of the lobar form in being more liquid, probably by reason of the smaller content of fibrin. The sputum was also richer in blood, which was usually of a light hue.

The examination of the blood was fairly uniform in regard to the absence of a leucocytosis, in fact the reverse was rather the rule, leucopenias occurring, with as low white counts as 2800, with some disturbance of the usual relationship, the neutrophiles suffering the greatest diminution, with a relative increase of the lymphocytic elements. Blood cultures were made in many of these patients, but were not productive of results, as in no single instance were we able to isolate an organism from the blood, nor did we find the Pfeiffer organism in the sputum in any of our examinations. The determination of the type of pneumococcus in sixty consecutive cases is a fairly accurate index of our series. In these sixty cases there were thirteen Type I, twelve Type II, three Type III, and thirty-two Type IV.

Urinary examination of these patients revealed no abnormalities, other than the usual febrile albuminuria and an occasional hyaline and granular cast. Bile pigment was found in several patients in whom there was present accompanying icterus, presumably of the hemolytic type.

At the beginning of the epidemic of influenza appearing in September, the mortality of bronchopneumonia was very high, approximately 35 per cent. There were no empyemas, as determined by physical examination, *x*-ray, and fifteen consecutive autopsies, nor did we note any involvement of the pericardium. From the middle of October to the present time (November 25), empyemas have been frequent, and pericardial involvement, especially of the fibrinous form, was found in a few instances.

This incidence of empyema in our more recent cases, associated with a more benign type of pneumonia and its absence in the more virulent and fatal form, seems paradoxical, but may find a possible explanation in the fact that the first group did not survive sufficiently long to permit of the development of complications. That empyema was absent, was proven by careful physical examination, the *x*-ray, negative results on aspiration, and finally by necropsy reports of lethal cases.

In the latter series of cases running a more favorable course, empyema was a fairly frequent complication, occurring in approximately 15 per cent. of the total number. The physical signs were often misleading, as on several occasions more than 1500 c.c. of pus was removed from patients in whom there still persisted definite bronchial breath sounds over a large area, with retention of tactile and vocal fremitus. In these the suspicion of an exudate was entertained from evidences presented of pressure on adjacent organs, augmentation of dyspnea, a septic type of temperature, presence of a Groccosign, fluoroscopy, and aspiration. It must be admitted that the *x*-ray and aspiration were not always infallible, as in several instances operation was performed with positive results, when the application of these tests yielded negative returns, despite the use of the most approved technique. Again, the enumeration of white blood corpuscles was often disappointing, showing no increase in proven pus formation in many instances.

In the majority of our cases pure cultures of pneumococci were obtained from the pus. In the more severely ill, the *Streptococcus hemolyticus* was often found in association. In one patient, with a very foul smelling pus, the *Bacillus proteus* was identified, and in another pus case of a greenish color the *Bacillus pyocyaneus* was present. In conjunction with the empyemas there were a few cases of pneumothorax. In one of these patients there was also a very extensive subcutaneous emphysema, involving the subcutaneous tissue of the face, neck, arms, and hands and extending over the entire trunk as low down as Poupart's ligament. Several other examples of the same character were observed, in which no intrathoracic collection of air could be demonstrated, nor presence of gas bacilli proven, nor evidences of rupture of the air passages determined.

In our series there were several with very marked cerebral disturbances, such as varying degrees of neck rigidity, maniacal manifestations, tendency to Kernig and Brudzinsky signs (and in

one individual the presence of a Babinsky and an Oppenheim) were suggestive of a possible involvement of the cerebral meninges, but as a lumbar puncture demonstrated no increased pressure, pleocytosis, globulin reaction, or presence of parasites in the evacuated spinal fluid, and the subsequent rapid evolution of these suspects to recovery forced us to conclude that they were rather a meningismus due to toxic irritation than an actual inflammatory process. The gastrointestinal tract presented phenomena in a large number of our series; an intractable emesis often ushered in the disease and was occasionally associated with a diarrhea in which blood was often present, although persistent examinations failed to reveal the usual organisms of dysentery. In some of these patients a very marked symptom was a severe and persistent pain in the abdomen, with rigidity, sometimes localized over the gall bladder, duodenum, or ileocecal region, simulating disease of these organs. One patient suffered from a complete obstipation for several days together with a marked distention and inability to pass flatus. These various phenomena often cause apprehension of some serious intraabdominal lesion and their pleuropulmonary origin may be overlooked, unless a thorough examination of the thoracic organs be conducted, suggesting the pleural reflex nature of these symptoms.

In the intestinal ileus patient the inference was that it was caused by the toxemia producing a paresis of the intestinal wall. In many some degree of circulatory disturbance was present, the most commonly observed being a tachycardia often associated with lowered blood pressure and diminished intensity of the cardiac sounds; extra systoles were not infrequent, and auricular fibrillation, when occurring, was of bad omen. Pericardial involvement was noted in several patients, but no clear evidence existed of recent endocardial participation, nor did a previously existing implication of the endocardium seem to render more grave the situation during the periods in which the individuals were under observation.

Convalescence was less protracted in our patients suffering from the lobar or croupous type. The tendency here was for the temperature to terminate by crisis, as contrasted with the lytic termination of the lobular pneumonias, which indeed were often so protracted together with persistency of rales at the apices, especially the right, and a continuance of a nocturnal febrile movement, that concern was occasionally experienced that the process might be of a tuberculous nature, especially when the bronchopneumonia was of an unilateral character. Again, the leucocytosis and herpes of the lobar forms were absent in the lobular type, and finally the mortality rate was greatly in excess of that existing in the lobar pneumonia.

Treatment consisted primarily in the institution of rigid prophylactic measures, patients were isolated in individual cubicles, the nasopharyngeal secretions were received in disinfectants, all individuals coming in contact with the sick were masked, wore gowns, on leaving patients carefully washed their hands, and as routine used an antiseptic mouth wash. During convalescence such patients as left their cubicles for any purpose were also compelled to wear the gauze face masks. Sweeping in the wards was done with sawdust or scraps of paper soaked in 0.5 per cent. lysol solution.

Living conditions of the detachment personnel received especial consideration, in regard to appropriate food, rest, hygiene, and prompt segregation of all persons exhibiting signs of acute respiratory derangements. Eating and drinking utensils were carefully washed. One of our most difficult problems was the enforcement of the antispitting instructions, as indiscriminate and promiscuous expectoration seems to be rather generally indulged in by our troops.

Direct treatment consisted in the early administration of a selected preparation of digitalis, given until physiological effects became manifest, then an interval of rest with a subsequent resumption of the drug. This routine requiring about thirty grams of a standardized tincture. Other measures consisted in instituting an appropriate dietetic regimen and the drinking of sufficient fluids the correction of gastrointestinal disturbances and the free administration of nature's oxygen, fresh air.

In a certain number of Type I patients, antipneumococcus serum was employed, but we were not convinced that such a procedure had a distinct value, although these patients progressed more favorably than those not treated with serum.

In view of the experience gained in the epidemic of 1917-18 we treated our empyema patients conservatively draining the pus by simple aspiration at intervals of several days until we felt assured that the resistance of the patient has been sufficiently raised and the danger of lung collapse was not to be greatly apprehended because of the establishment of adhesions before proceeding to the more radical operation of rib resection.

When signs of cardiac incompetency became apparent venesection frequently afforded relief and in certain instances was a life-saving device especially when pulmonary edema was imminent. Sterile camphor oil and intravenous injection of adrenalin were occasionally found of value when we were confronted with evidence of a failing circulation.

Under the existence of conditions which prevailed throughout the A. E. F. it was not possible to carry on effectively a study of blood acidosis but this subject affords many interesting phases for solution, especially in regard to the therapeutic value of intravenous administration of glucose and alkaline solutions.

THE USE OF HYPNOTISM IN THE TREATMENT OF PSYCHONEUROSES.*

By JOHN McD. McKINNEY, M.D.,
ANN ARBOR, MICHIGAN.

It might be well at the outset of this paper to establish a precedent for the use of this agent of therapy as there are undoubtedly some to whom such a method of argument has its appeal. Probably the earliest account of hypnotism, as a therapeutic agent dates back to the Egyptian medicine of 1552 B.C., as revealed by the Eber's Papyrus which describes physicians of that period as healing patients by the laying on of hands. We are indebted to the ethnologist, Stoll, for consid-

*From the Neurologic Clinic, Hospital of the University of Michigan, Ann Arbor, Mich.

erable evidence of the use of this method among the early Oriental races. In considering the history of hypnotism it is well to bear in mind that the early employment of this method was surrounded with much mystery and superstition, and it has been a struggle from the earliest times for hypnotism to gain credence among the more conservative members of the medical profession. Such men as Paracelsus, 1530, Van Helmont, 1560, Maxwell, 1600, Stantanelli, 18th century, and Mesmer, 1734-1815, who were most influential in the development of this subject were looked upon as charlatans by the contemporary scientists of their periods. No doubt their methods did savor of quackery but nevertheless they employed a scientific principle which, though sought for from time to time by many learned commissions, especially in France, was never recognized. Only occasionally, and then quite lukewarmly, did the medical profession take hypnotism seriously. Du Poete, 1820, was the first to employ hypnotism in hospital practice. Subsequently Mesmerism, as such, was employed for quite awhile in the hospitals in Germany. In 1841 Braid and others labored to introduce hypnotism as a means to painless surgery. In America, Grimes, Darling, Durand deGros, and Beard used hypnotism therapeutically in the last century. Finally Liébault and Richet put this method on a scientific basis in Paris in 1875. Charcot and his pupils, among whom were Binet, Féré, and Babinski, took up this work at the Salpêtrière in 1878. Then came the establishment of a professorship of Hypnotic Therapeutics at the Medical School at Nancy, in 1884. Professor Bernheim held the chair. There then arose in France two schools of thought as to the nature of hynotism. The one at the Salpêtrière and the other at Nancy. The one at Nancy eventually won out, and is now universally accepted. In recent times the establishment of hypnotism in a position of respect among the practitioners of medicine has been greatly furthered by a special committee appointed by the British Medical Association to investigate this question. Such psychologists as Preyer, Münsterburg, Krafft-Ebing, and James have done much to stabilize thought in regard to this phenomenon.

Bringing the subject of hypnotism up to more or less recent times, I find that the following men have used it to advantage in the treatment of the psychoneurotic conditions incident to the late European war: Feiling,[1] Hurst and Ormond,[2] C. S. Meyers,[3] Hertz,[4] Tombleson,[5] Brown,[6] Smyly,[7] Ballard,[8] Eder,[9] Russell,[10] Podiapolsky,[11] Rorschbach,[12] Nonne,[13] Oppenheim,[14] Smirnoff,[15] Howland,[16] Craig,[17] Fearnsides,[18] Wakefield,[19] Wagner,[20] Prümers,[21] Rivers,[22] and Read[23] used this method successfully. Elliot and Pear,[24] Southard,[25] Ames,[26] Salmon,[27] and an editorial writer in the *British Medical Journal*,[28] advocate its use.

More particularly in this regard are to be mentioned Myers, Brown, Eder and Nonne. Myers, in summing up his results under hypnotic treatment, reports: Apparently complete cures 26 per cent., distinct improvement 26 per cent., failure to hypnotise 35 per cent., no improvement after hypnosis 13 per cent. Eder in a series of seventy-nine cases reports 70 cured, 7 improved, 2 unchanged. Nonne gives the following advantages of hypnotic suggestion, as the result of his employment of this method in connection with war hysteria: (1) Cures were frequent and rapid. (2) Hypnosis may be regarded as a means of differentiation between organic and functional cases. (3) Cases of stubborn tremor and tics of long duration, as well as severe vasomotor disturbances were promptly healed by suggestion. (4) Hypnotism would be of great value in determining the disability of the individual, the degree as well as the duration, so that he could be returned to duty if he is fit for duty. Brown, more recently, in his article in *The Lancet* of August 17, 1918, recounts the successful treatment of two hundred and ninety-four cases by his modified hypnotic method.

Turning to the practicability of this method of treatment, we find, in the first place, that cases for treatment must be selected; but this is in no sense an objection to its use. Selection implies merely a careful diagnosis, which is or should be, essential to any mode of therapy. The psychoneuroses are divided into three great subdivisions. Pithiatism,[1] the first of these subdivisions, is, by definition, produced and curable by suggestion and is most amenable to cure by hypnosis, Pithiatism is a definite clinical entity. It has definite signs, requires a definite diagnosis, and should not be diagnosed by exclusion as the average medical man is wont to do. We are all too familiar with those cases in which the diagnosis is obscure and the presence of an organic basis for the disease is not apparent, that for want of a better diagnosis are labeled hysteria. The other two subdivisions, psychasthenia and neurasthenia, are likewise clinical entities and are in no way synonymous with each other or with pithiatism though used as such even in neurological literature. In the treatment of cases of neurasthenia and psychasthenia, hypnotism plays a minor part although it may be of use when necessary to allay night-mares and dreams which are terrorizing and exhausting the patient.

As to the technique it is simple and not at all difficult to acquire. The details of technique may be found in any good book on hypnotism. There are, however, a few details which I have, in my experience, found important enough to bear emphasis. Avoid fixation of the eyes, whenever possible, as it leads to disagreeable after-symptoms of fatigue. The main thing that is essential to the successful employment of this method is confidence on the part of both the patient and the doctor, and this is only to be gained through correct diagnosis and the ability of the doctor to convince the patient that he knows what he is doing. I have found it best not to use the word hypnotism, but to explain to the patient that the treatment consists in securing in him a condition of complete rest and relaxation followed by sleep. I then proceed to get at the heart of the patient's trouble by using hypnosis as a short cut in psychoanalysis. A light hypnosis is all that is necessary, and in fact, the patients are sometimes in touch with their environment. I then repeat over and over again to the patient that his symptoms will disappear and that when he awakens

he will remember what is being said to him. I assure him that his symptoms will disappear on awakening and that they cannot possibly return. The attention to detail during this stage cannot be over emphasized. The choice of words and the tone of voice are especially important. To illustrate, in one of our cases in experimental psychology we presented a bottle of ammonia to the patient to smell, telling the subject that it was a violet perfume. We then asked, "Is it not sweet," the patient recoiled from the bottle in response to the nasal irritation and replied "No." However, when we presented the bottle again saying, "Here is a bottle of violet perfume which I want you to smell, its odor is delightful." The patient apparently took great satisfaction in smelling of the contents. Similarly in the suggestions given to the patient for therapeutic reasons the choice of words and the tone of voice must be such as to permit not the shadow of a doubt that the symptoms can return.

The awakening of the patient is of utmost importance. I tell them that they will wake up gradually while I am talking to them, bringing in reassurances, incidences in their past experiences, and objects of their present environment to reestablish their associations.

Cases in civil life differ from the war hysteria cases, in that they are usually of longer standing and the patient's resistances and rationalizations are more strongly and more complexly developed. For this reason several sittings are usually necessary to get the desired results.

In a series of cases in this clinic 15 per cent. of the cases of pithiatism on which we have tried this mode of therapy proved refractory. It was noted in these cases that there was a great distractability of the attention and the failure in these cases I think may be safely attributed to erroneous technique. An interesting discussion in point, bearing upon the susceptability to hypnosis, is to be found in a series of communications to *The Lancet*[29] by Doctors Core, O'Brien, and Brown. They practically agree with Bernheim[30] that 80 per cent of all people are hypnotisable, that is that 80 per cent of all people are sufficiently suggestable to be hypnotised. Necessarily all of the class of people suggestable enough to be called pithiatic must be subject to hypnotism. All that remains is to develop the proper means of fixing their attention. As it stands, the large majority of pithiatical patients submit readily to hypnotism and I believe that with further refinement of technique the small percentage of refractory cases may be still further reduced.

If this method is a valuable one, undoubtedly the question arises as to why it is not more universally accepted. Many writers refer vaguely to the objections to hypnotism, but few stipulate them. Arnstein,[32] Mott,[33] Adrian and Yealland,[34] Hunt,[35] Holbrook,[36] Trotter,[37] and Liébault,[38] advise against its use. Chavigny[39] writes that it is prohibited in French military hospitals, and Bochi,[40] in his review of the French work, remarks upon the failure of the French to utilize this method. Nowhere, however, do I believe are these objections better summed up than by the distinguished French neurologist, Dejérine.[41] I shall take these objections up one by one and endeavor to refute them at the same time. (1) Hypnotism requires a limitation of consciousness. This we cannot deny, but I must ask, is there any method of suggestive therapeutics that does not require the same thing? (2) There is a liability to dangerous suggestion. This is also undoubtedly true, but nevertheless dangerous suggestions are not so subtle but that they might be avoided by the employment of moderate precaution on the part of the operator. (3) Other means of therapy work as well. This is true only to a limited extent. I do not claim for hypnotism that it is a panacea, nor is it my object to belittle other means of psychotherapy. I further believe that the use of such methods as galvanism and reeducation should be in some cases used along with hypnotism, as I believe that in this way I get a synergistic action where the employment of one means alone is liable to failure. As I have already intimated, psychoanalysis should always be used along with hypnotism wherever possible. It is interesting to observe that the so-called waking suggestion, as suggested by Dejérine,[41] is not very widely different from a modified method of hypnotism. (4) Hypnotism is objectionable on ethical grounds inasmuch as the operator may be a man and the subject a woman. This objection, however, may be easily obviated by the presence of a third person. (5) Dejérine suggests that even worse symptoms may be brought on by the depression of the patient caused by the knowledge that he is hypnotisable. This is a point made much of by the adverse critics of this method of treatment, in that they say it is dangerous to the morale of the troops. I believe that I avoid this objection by not using the term hypnotism at all in connection with the treatment, as I have suggested above. (6) Cases must be carefully selected. This objection, I believe, I have met in the foregoing part of the paper. (7) Hypnotic suggestion is unassociated. Dejérine very truthfully remarks that the value of a mental acquisition is measured by the number and variety of ideas with which it is associated. He further goes on to state that frequent repetition may assume the same proportions. Now since this is the case, in giving our hypnotic suggestion, we particularly emphasize the frequent repetition and further, by means of psychoanalysis and our method of awakening the patient we are enabled to associate the suggestion with all the ideas that may be necessary for it to become of therapeutic value. (8) The patient tends to become an automaton, and the faculty of autosuggestion is increased. I believe that Dejérine, in holding forth this objection, had mainly in mind the patients of Charcot at the Salpêtrière. These subjects were undoubtedly automatons, for they were victims of psychological experiments in which it was the object of the operator to obtain greater dissociation and even dissociated personalities rather than to preserve the associations of the patient. These patients were repeatedly hypnotised and all the evils laid to the door of hypnotism obtained in these cases. But with my method of awakening the patient and of hypnotising them only a sufficient number of times to achieve the desired results, I do not believe that such an objection would prove to be

valid. (9) The action of hypnotic suggestion on regaining consciousness is illusory. The permanence of the effect of hypnotic suggestion is measured by the number of ideas with which the suggestion is associated, also with the number of repetitions of the suggestion as I have pointed out above. The so-called defense theory of Freud is a possible explanation of the lack of permanence of the hypnotic cure; however, if a psychoanalysis is obtained by the use of hypnosis, as we have suggested, there will be no necessity for other defense symptoms developing.

The fact that the French have used it very little if at all during the recent war may or may not be an objection, depending upon what their reasons might be for so doing. In a careful search of the literature I have been unable to find any further objections than those which I have just given above. There is a more subtle reason which I believe has had a great deal to do with the lack of general acceptance of this mode of therapy, and this has to do with the origin of hypnotism, and the ill repute in which this method has always been held by the medical profession, as I have endeavored to point out in the opening paragraph of this paper.

To conclude, I believe that hypnotism is a valuable asset to the physician who has to deal with cases of pithiatism. Like all instruments it requires some discretion and judgment on the part of its user. But these elements as applied to hypnotism are no more elusive or difficult to acquire than is demanded by any other specialized mode of therapy, nor does it require the elaborate system and preparation that characterize the large plants in which the more popular methods of re-education and waking suggestion are employed. Hypnotism is a valuable and scientific means of psychotherapy and should have its place in the medicine chest, so to speak, of every psychotherapeutist.

THE TREATMENT OF GASTRIC ULCER BY RECTAL INJECTION OF SUGAR.

BY GEORGE W. GREENE, M.D.,

AUBURN, N. Y.

MOST physicians give beef tea as a rectal enema, notwithstanding the fact that Dr. Dalton showed a good many years ago that a puppy would die, if fed on it, a day sooner than if fed on water. Some physicians give peptonized milk. I have given this treatment a number of times and I found that, if the rectum was washed out an hour later, the milk would come away as a curd, not being absorbed at all.

If a physician is consulted for ulcer of the stomach, he will give a long list of articles to be eaten. I can not see how an ulcer of the stomach can be cured while you are feeding the patient, for the digestion fluids will digest the ulcer. I know from experience, however, that they frequently are cured in that way. If you consult a surgeon he will invariably recommend an operation. I know one instance in which a gastroenterostomy apparently resulted in the cure of a bad case of ulcer.

For a long time I have treated ulcer of the stomach by sugar enemata. I starve the patient for two weeks and feed him by giving rectal injections of sugar. Three teaspoonfuls of sugar are dissolved in one glass of water; of this solution I give a syringeful which holds 1 oz., every 10 or 15 minutes.

I will relate one case. Mr. B., a bookkeeper, had had stomach trouble for some time. He would eat a hearty meal, and in about three hours he would have severe pains which could be stopped by eating. There was also tenderness below the ensiform cartilage. I starved him for two weeks, feeding him with sugar by the rectum. It was remarkable how well he bore the treatment. He did not suffer for food at all. I first gave him one-half glass of milk three times a day and the following day gave him a whole glass of milk; on the third day I gave him a glass of milk with one egg beaten in it. The next day I gave him a full meal. The treatment was perfectly successful, resulting in a permanent cure.

Military Medicine.

New Estimate of Casualties in American Expeditionary Forces.—A casualty list of the American Expeditionary Forces in France, which is practically complete, was issued by the War Department on April 3. According to this estimate, the number of Americans killed in action, including 381 lost at sea, is 32,178. Other casualties were as follows: died of wounds, 13,412; died of disease, 22,326; died of accident and other causes, 3,980; missing in action, 5,019. The total number of deaths from all causes is 71,896. The number wounded in action is 194,362, while the total number of casualties to date is 271,277.

Army Doctors Accused of Negligence.—A circular recently published by the Chief Surgeon of the American Expeditionary Forces charges that some medical officers have been "grossly careless and neglectful of their duties" in the matter of the prevention of typhoid and paratyphoid fevers in the overseas army. The chief surgeon cites many instances where epidemics prevailed among troops, especially during the last offensive on the western front, and points out that the occurrence and distribution of diseases was constantly brought to the attention of medical officers through weekly bulletins. The circular states that many officers failed to grasp the significance of these reports and warnings, owing to a false sense of security due to the belief that vaccination against typhoid and paratyphoid gave complete immunity even in the midst of grossly unsanitary conditions. Both dysentery and typhoid fever are said to have prevailed to some extent after the St. Mihiel offensive but their significance was overshadowed by the epidemic of pneumonia and influenza prevailing at that time. This circular reports that one replacement unit of 248 men from Camp Cody, N. M., reached England with typhoid fever prevailing extensively; 39.5 per cent. of the unit had the disease and the case death rate was 8.42 per cent. The unit had been vaccinated a few months prior to the epidemic.

Health of Troops Continues to Improve.—Official health reports issued by the War Department on April 2 show that the health of the troops both in the United States and abroad has continued to improve. The rate for pneumonia in the report for the week ending March 13 was about one-half that of the previous week. The number of non-effectives overseas on the above date was 67,605. From November 14 to March 13 13,365 deaths from injury have been reported overseas, of which 12,533 were from battle wounds. During the last week in March, 47 deaths from wounds received in action were reported.

Capt. Thomas Cassidy of Spencer, Ind., who was a medical student at the University of Chicago when the war began and who went overseas as an ambulance driver three months before his graduation, and later became an aviator, has been decorated with the Distinguished Service Cross, the Cross of the Legion of Honor, and the Croix de Guerre.

High School Honors Doctor Who Died of Wounds.—The Jordan High School of Lewiston, Maine, had dedicated the March number of its school publication to the memory of Major Howard W. Beal, who died of wounds in France on July 20, 1918.

Casualties Among American Medical Officers in France from the time of the arrival of the first units to March 13 numbered 443. A War Department statement shows 46 were killed in action, 22 died of wounds, 12 died of accident and other causes, 102 died of disease, four lost at sea, seven missing in action, 38 taken prisoners, and 212 wounded in action.

War Risk Insurance Takes Over Camp Hospitals.—An extensive program providing for the care of disabled soldiers after their discharge from military service has been announced by the War Risk Insurance Bureau. Twenty-one hospitals with a capacity of 1,500 beds are already in use and the War Department has turned over to the Treasury seven camp hospitals for the care of disabled soldiers. These are to be enlarged and improved out of the $9,000,000 fund appropriated for hospitals for disabled soldiers to be controlled by the War Risk Insurance Bureau and conducted by the Public Health Service. All soldiers 10 per cent. disabled from causes suffered in the line of duty are entitled to compensation and treatment by the Bureau of War Risk Insurance. Men who after discharge develop physical disabilities attributable to military service are entitled to treatment. The hospitals which the War Department has turned over to the Treasury Department are located at Camp Cody, New Mexico; Camp Hancock, Georgia; Camp Joseph E. Johnson, Florida; Camp Beauregard, Louisiana; Camp Logan, Texas; Camp Fremont, California, and the camp at Perryville, Md. About $750,000 will be expended for enlarging and improving these hospitals. The Treasury Department has purchased the Speedway Hospital in Chicago, with a capacity of 15,000 beds. Improvements and changes costing $500,000 will be made in the hospital and it is planned to make it a national center of medical study and research. Portions of the Battle Mountain Sanitarium at Hot Springs, S. D., and a hospital at Corpus Christi, Texas, have been taken over for the War Risk Insurance Work. The sum of $1,500,000 will be expended in the erection of a hospital at Dawson Springs, Ky., and other hospitals will be erected at Norfolk, Va., and in or near the District of Columbia. The Marine Hospital at Stapleton, S. I., will be taken over and $190,000 expended in improvements.

Deaths in the Service.—Capt. WILLIAM W. WALCOTT, M. C., U. S. Army, of Natick, Mass., regimental surgeon of the 101st Engineers, died in France, on March 16, aged 39 years. He was a graduate of Harvard Medical School in 1905, and a district health inspector under the Massachusetts State Board of Health. During his service on the western front last summer he was wounded and gassed, after which he spent a month in the hospital on account of injuries.

Lieut. HARRY AUGUSTUS SCHEPPACH, M. C., U. S. Army, of Newark, N. J., a graduate of Bellevue Hospital Medical College, in 1898, on duty at the Yale Army Laboratory School, New Haven, Conn., died in New Haven from typhoid fever, on January 29, aged 43 years.

WAS INFLUENZA EVER ENDEMIC BEFORE 1890?

THE statement is being made unchallenged that endemic winter grippe dates only from the pandemic of 1890. A survey of the annual indexes of the MEDICAL RECORD for some years previous to that year, taken in connection with the testimony of old practitioners, appears to make this claim good, at least so far as New York City and the Eastern seaboard States are concerned. Nevertheless a little investigation has shown that in certain parts of the world endemic winter grippe had prevailed prior to the year 1890. It readily appears that in parts of France grippe occurred almost yearly during the 80's, and that in our own country it was an almost annual winter visitor in Minnesota, at least, during the same period. The nearest approach to a pandemic before 1890 was in 1879, in which year the disease prevailed notably in certain parts of the United States and other countries. Still further back we find scattered epidemic incidence in 1874-5 and in 1871. But we are not interested in this connection in the strictly epidemic incidence. All goes to show that in the 80's, with the exception of parts of France and our Northwest, there was a notable absence of the disease in whatever form and incidence. In the *Index Medicus* for 1890, the second year of the pandemic, the list of names of authors of papers on the disease occupies in fine print nearly a column in the index of names. In 1889 there were but four papers indexed, one of which was by Dr. Merrill of Stillwater, Minn., which will be discussed later. Two others were by French and the fourth by a German author. The European articles were relatively insignificant. In 1888 not a single title was indexed. In 1887 three French articles were indexed, which indicated plainly the presence of a severe type of grippe in France, while in 1886 the number of articles indexed was five, three by French and two by Australian authors—for there was an epidemic of influenza in the latter country in 1885. The *Index Medicus* for 1885 contains but two unimportant French references to the disease. An analysis of the French articles which appeared between 1885-1890, or up to the time of the pandemic, shows conclusively that grippe was endemic in parts of France, including Paris, and was a serious affection. No less than three graduation theses appeared on the disease during this period in addition to a special monograph. The subjects were as follows: Epidemic of grippe at Rochefort in 1886; modalities of grippe; pneumonia and bronchopneumonia following grippe, and pleurisy of grippal origin. In addition there were two clinical papers on pleurisy complicating grippe, one dealing with empyema.

The words epidemic and endemic should not be confused in this connection, for they do not exclude one another. When winter grippe appears in a community in massed incidence we may call the episode an epidemic, but when it reappears with each succeeding winter we come to regard it as endemic for the locality. Moreover, in true epidemic incidence the disease is contagious and rapidly spreads to neighboring regions, which behavior is not seen in the purely endemic form. To obviate confusion writers may call winter grippe endemo-epidemic when it approximates the diffusible form.

We come now to the rather remarkable paper which was read by Dr. Merrill of Stillwater, Minn., in June, 1889, before the advent of the coming pandemic was dreamed of. This writer states plainly that local epidemics of influenza prevail in Minnesota "almost every fall and winter." One form, the enteric, passes under the name of "winter cholera." The disease, which is often unrecognized, does a vast amount of mischief, which passes unnoticed because physicians fill out death certificates with the complication, as lobar pneumonia, bronchopneumonia, and, in young children, convulsions. If space permitted we would like to quote extensively from the doctor's almost classical paper, which appeared in the now defunct *Northwestern Lancet* for 1889. It hardly seems reasonable that Minnesota could have been the only part of the continent of North America which suffered annually from grippe and a study of the mortality curves of other regions would doubtless, if expertly analyzed, show that numerous others were involved. The older clinicians could not have overlooked the highly diffusible and contagious influenza, but the endemic type, coming in the open season for bronchitis, pneumonia and pleurisy, is much more elusive.

ACTION OF THE *X*-RAYS ON THE CHRONIC LEUCEMIAS.

THERE is both a quantitative and a qualitative action of the *x*-rays on the blood. The number of white cells progressively decreases in striking proportions and in one case of myeloid leucemia Beaujard noted that in seven months the number of white cells per cubic millimeter dropped from 235,000 to 5,400. This leucocytic drop continued for several days following the application of the rays. From the qualitative viewpoint, the destruction is especially evident for the myelocytes, their proportion dropping from 50 per cent. to 1 or 2 per cent. in a few weeks. At the same time, the number of erythrocytes rapidly increases to such an extent that in a month the increase may amount to one million. This rise in

red cells is not parallel to the inverse phenomenon observed in the whites, for when the influence of the irradiations appears to have become spent on the leucocytes the rise in the number of red cells will be found to continue for some time longer.

The size of the spleen diminishes astonishingly because in a few months a spleen almost filling the abdomen may be reduced to a practically normal size. In other cases the reduction takes place more slowly. The same retrogression in the lymph-nodes likewise takes place. From ten to twenty days at the most after beginning the treatment the general health is sensibly ameliorated, the edema subsides, and the patient's appetite returns. This improvement does not necessarily coincide with a return of the blood to the normal, but there nevertheless is a close correlation between them. The improvement in health persists as long as the number of erythrocytes is on the increase, which indicates that the *x*-rays continue their beneficial excitation of the formative organs of the red cells. The activity of this hematopoietic elaboration is the principal act; the drop in the white cells is secondary, as analyses of the blood, when compared with the variations in the patient's health, will show.

Among the mechanisms offered for explaining the action of the *x*-rays in the leucemias, it has been supposed that they destroy the "morbid elements" and toxins secreted by these elements; but even should this conception be adopted, it must be admitted that no data of positive observation can be invoked in confirmation of such a view. If the conception of a bacterial action were admitted if the leucemia were really caused by infectious germs, how could the cure or amelioration in the health be explained? In these circumstances it must be supposed that the rays favor the process of immunization of the organism against the causal infection, but until more ample information is at hand the results of experience alone should be taken into consideration, and we know of no bactericidal action resulting from the *x*-rays applied in therapeutic doses at present employed.

It is generally conceded that the decrease in the number of leucocytes results from their progressive destruction, because after a few exposures of the rays numerous degenerated leucocytes are found in the blood, while the increase of uric acid in the urine clearly testifies to this. A number of competent writers explain this destruction by the formation of a leucotoxin or a special lysine which results either from a biochemical change in the lecithin of the white cells or from cholin, an active product resulting from the splitting up of lecithin. That such a leucolysin exists has been proven and that it is produced in normal subjects exposed to *x*-rays has been demonstrated by Ambrozio, but instead of attributing an all powerful curative action to the *x*-rays in leucemia, it would seem more logical to assign to them a simple exciting action on the defensive functions of the organism by stimulating the hematopoietic organs.

This mechanism has been explained by Roch. The spleen is the center of the formation of both red and white cells and is also the center of destruction of both, therefore it possesses four centers. An untreated leucemia is the result of an exaltation of the centers of white cell formation and destruction of red cells, and *x*-ray treatment attenuates their activity and at the same time stimulates the center of red cell formation and that of white cell destruction. Why this selective action of the rays? All four centers are stimulated, but the center of white cell formation and that of red cell destruction having reached a functional paroxysm on account of the morbid process, no longer respond to the stimulating action of the rays, while the other two, previously inactive, react with all their latent energy and an equilibrium becomes established. This conception has the advantage of being derived from physiology, while it is also compatible with the theory of the leucolysins, but in this case these are regarded as products of secretion of the macrophages of the spleen which enter into hyperactivity under the influence of the *x*-rays. All these hypotheses are laudable scientific efforts, but the subject has only begun to be studied and further work must be undertaken before any definite conclusion can be arrived at.

MEDICINE AND POLITICS.

MEDICINE and politics seem to be in the very nature of things antagonistic. In this country, perhaps, more so than in any other land, because following politics here is a good deal of a profession. Therefore, the medical man in politics is first and foremost a politician and is seldom elected to either federal or State legislature with the view of suggesting or urging the passage of laws in the interests of public health. The American political medical man is entirely merged in politics. In fact, the medical man in politics in America is practically a negligible quantity so far as being influential in promoting public health or the interests of medicine.

Unfortunately, although in a less degree, a similar state of affairs exists in Europe. In Great Britain, for example, it is now fully recognized, a lesson which the war has driven home, that the health of the masses should come before everything. Indeed, that it is quite the most important phase of administrative government. Now that British statesmen or politicians have come to a complete realization of the self-evident truth that no nation can prosper unless the general health of the population is good, it has been decided to form a Ministry of Health. One would imagine that in order to conduct the duties of such a ministry with success it would be necessary to have in Parliament a considerable body of medical men, and especially of those well versed in preventive medicine. This appears to have been the idea of the large number of members of the medical profession, who offered themselves as candidates for election on the grounds that they would be required in parliament to give expert advice as to the constitution of a Ministry

of Health and particularly with regard to its duties. The result has been deeply disappointing, for while some medical men of eminence were elected to the new Parliament, mainly on account of their prominence, and others were reelected who had made reputations as politicians, and while a few with strong personal or local claims came in with the flowing tide, yet it cannot be stated with confidence that in any one instance the returned member sits as a purely medical representative. Indeed, as in former British Parliaments, the medical members possess a political rather than a professional status. Certain of the medical men who are M.P.s are notoriously party politicians who owe their power to that fact and not to their professional abilities or to the trust placed in them by the medical profession.

There are two sufficient and valid reasons why medical men here and in Great Britain do not wield the influence they ought to wield when medical legislation is under consideration. One reason is that party politics is all powerful, and another is the lack of organization in the medical profession. That is to say, Ministries of Health should put into effect the object for which they have been created, to improve the public health, and not merely to add another national bureau in order to be able to reward faithful but greedy henchmen with lucrative offices therein. Moreover, medical men cannot expect to be appointed legislators unless they are loyally backed by a wholly united profession.

At the present time no form of reconstruction is as essential as human reconstruction, and so long as housing is inadequate, defective, and unsanitary, and unsanitary conditions prevail generally, just so long will ill health, discontent, and unrest prevail. A contented people do not create disturbances, but a people will never be contented while intolerable conditions of living exist on a large scale. The carrying out of measures calculated to decrease disease and to improve the physical well being of the community at large would prove a panacea for untoward economic conditions, and is to be advocated from every standpoint. In a campaign for the teaching and enforcement of healthful methods of living, the medical man, by virtue of his expert knowledge, should of necessity take the first place.

DERMATOPHOBIA.

Of all the many phobias, dermatophobia is probably one of the commonest, as dermatologists can attest. Cutaneous obsession is met with in young people only when they have received suggestion from their parents, usually the mother, and is unquestionably more common in cities than in the country towns for reasons too obvious to mention. Besides the well-known general causal factors common to all phobias, an occasional factor is also necessary which shall direct the morbid emotion that it has created. The latter factor is to be found in the perusal of certain kinds of literature, a conversation, or the sight of a cutaneous lesion. Medical opuscules and journals circulated with a so-called humanitarian object singularly favor the researches of these subjects in quest of medical knowledge. In other instances the patient suspects that he or she has some abnormal bodily condition, and in this case the mirror plays an important etiological part. This is what usually occurs in trichophobia, since the treatment of hypertrichosis by electrolysis and the *x*-rays has come into vogue. Of particular frequence is dermatophobia from fear of contamination in the barber shop. Contagion in this case is certainly possible, and the apprehension that it inspires is quite legitimate when not carried too far. The newspapers and measures taken by the health authorities have awakened fear in the public mind in respect to contagious diseases, and the result has been an ever increasing number of cases of dermatophobia. Frequently the morbid mental state develops after direct contact with a person supposed to be diseased. Thus a person believes he has contracted scabies because he has touched the skin or clothing of some one supposed to be the host of the busy little parasite, and so it goes.

Finally, dermatophobia can be communicated from one person to another by simple suggestion. For example, in one case a husband, believing that he was afflicted by a pruriginous skin affection, passed this belief on to his wife. In another case a mother who supposed herself afflicted with a cutaneous disease transmitted her dermatophobia to her daughter by mere suggestion. A yet more interesting example was that of a woman who had contracted a psychic pruritus and by suggestion mentally contaminated her son, niece, nephew, and their children, the sum total of transmitted dermatophobias in the family amounting to eight persons. Cutaneous obsessions can be transmitted from animals to man, this genesis being almost exclusive for parasitophobia; and lastly, an important cause of dermatophobia is to be found in pruritus with all its many origins. Pruritus has as principal causes a state of cutaneous hyperesthesia, direct local irritation produced by irritants acting on the cutaneous surface, subcutaneous irritations resulting from diseases or their effects, toxic or otherwise, local nutritive disturbances, and, last but not least, spasmodic contraction of the tensor muscles of the hair. The latter is, *per se*, a sufficient cause for the development of dermatophobia.

The conclusion is that the cause of the pruritus which gives rise to dermatophobia will frequently escape detection, in which case the phobia will be erroneously diagnosed as primary, and it appears logical to assume that dermatophobias without a substratum must represent a very small percentage of cases. It is not improbable that the so-called purely psychic cutaneous obsessions may result from trophic changes in the skin, the nature of which is as yet to be determined. It must be recalled that many of these patients are neurasthenics and arthritics, that is to say, candidates for arteriosclerosis and certain sclerous lesions have been found among them. All these considerations require

more ample verification, but they leave the impression that every case of dermatophobia possesses a material basis, and it is probable that one will not go far from the mark in admitting that a dermatophobia without a substratum does not exist.

CLINICAL HEMATOMETRY.

ONE of the most important of our clinical methods is the estimation of the hemoglobin content of the blood and yet the methods in general use for this procedure leave much to be desired in the line of accuracy. Hematometers in general are of two types, those which utilize for a standard a permanent color, ruby glass, for instance, which is of a different nature than that of the blood with which it is compared, as seen in the Miescher or Dare apparatus; and those which utilize a standard which is identical in nature, and therefore color, but which unfortunately is not permanent, such an apparatus as the Sahli. Furthermore the element of time, in the use of the latter apparatus is usually neglected. It is probably a safe statement that the majority of the hemoglobin estimations made, even in hospitals of good standing, have an error of fifteen per cent. or more. The oxygen capacity method of Van Slyke is highly accurate but is not a clinical method. These facts are emphasized by Newcomer in an article on the Absorption Spectra of Hemoglobins appearing in the *Journal of Biological Chemistry*, 1919, xxxvii, 465. He demonstrates that it is exceedingly difficult to find artificial matches for hemoglobin solutions because the absorption curves of the materials do not correspond with those of the solutions. Even in the Miescher instrument which has been considered the best of the hematometers, the curve of the glass standard only roughly approximates that of oxyhemoglobin and then only under fixed conditions of illumination. But he was able to find a glass, the "high transmission yellow" semaphore glass, which has an absorption curve with white light which very closely approximates that of acid hematin. When this is used with some colorimeter of the Bubosq type it is possible to get accurate readings quickly and easily.

It has been known for some time that solutions of acid hematin do not acquire their full color depth immediately and some authors have endeavored to compensate for this by making their readings at a fixed interval after adding the acid. Newcomer has developed a formula which does away with inaccuracies due to the time element. This is expressed as $xy = -40$ where x is the time in minutes and y is the per cent. by which the acid hematin falls short of its full color depth. y therefore is equal to $-\frac{40}{\text{time in minutes}}$ and this percentage should be deducted from all readings made of acid hematin solutions which are less than forty minutes old. Tables are given for use with pieces of glass of varying thickness and for translating the results into percentages. These findings not only furnish us with a quick and accurate colorimetric method for the estimation of hemoglobin, but also a method for the standardization of apparatus now in use, so that the rough approximations of the past will no longer be excusable. Chemical methods are increasing in accuracy and delicacy continually and it is hoped that this clinical method will find ready adoption until some better one appears.

THE DANGER OF MINISTERING TO SUPERSTITION.

BY reason of the fact that his lightest utterance anent matters in any way pertaining to health is taken by the laity as *ex cathedra*, the physician must be over-scrupulous how he acquiesces in popular fallacies. Early in his professional career a general practitioner learns diplomacy and psychology of the most practical sort. When he finds that the revered grandmother of the family has been applying therapy of the 1850 variety he must steer between the Scylla of retarding his patient's recovery and the Charybdis of offending the conceit of an influential adviser and an eventual loss of practice. He therefore learns to steer a middle course by agreeing verbally with the lay theories, but modifying the application as much as possible and insinuating gradually his own therapy. But when it comes to the question of a pet superstition, there is danger that his complaisance may lead him to a confirmation—which inevitably results in fixing the fallacy irrevocably—especially since there may seem to be involved no question of danger to the life or health of an individual. Often indeed these superstitions seem more fantastic than harmful, they are perhaps a matter of faith and have been maintained earnestly by the holder, who looks to his family physician to support him.

We are able to get a proper perspective on a question of this sort only by considering the function of the physician in society, which is broader than the alleviation and healing of disease; he is bound to disseminate knowledge and dispel ignorance in regard to matters pertaining to health, sickness, prevention of disease, etc. It is not on record that superstition ever led to good and it is impossible to estimate the amount of harm done by the spread of even one commonly held fallacy, leading as it may to fear states, with their accompanying psychic and physiological changes.

We are all familiar with the stories of prenatal frights with their resultant reproduction in nævi —the pregnant woman frightened by a mouse and the mouse-shaped birthmark, etc. Recently there was reported before a medical society the case of a child born with the osseous structure of the left chest missing, and this was attributed to an accident sustained by the mother when seven months and eighteen days pregnant! One might be led to wonder if the essayist had ever seen a fetus during the eighth month and if so, how he imagined a trauma would act which would cause half the chest

wall to involute, so to speak. No doubt in the case in question the relatives will make a family legend out of it—it will go down from father to son for many generations and be made the text and paradigm of many a lay discourse. And many and many a pregnant mother, stumbling over a wrinkled rug, or running against a table in the dark, will lie awake picturing horrible, monstrously deformed offspring. Let us then disseminate light rather than gloom and help the world to reason rather than to fear.

Symbiotes.

This term is applied by Portier in a monograph with that title reviewed in *La Presse Médicale* for February 14 by Desfosses to such bacteria as are constructive to the physiological processes of the organism and not antagonistic or indifferent. He apparently prefers the term symbiote to the older symbion. The conception of symbiosis extends deeply into organic existence and the author is at pains to show that a species of termite in Madagascar in constructing an ant-hill carries out the basic principles of constructive symbiosis. Certain special woods are sought and utilized and the dead wood is eaten and assimilated by the ants and the undigested residue which consists of pure cellulose accumulates in the form of cakes of a porous character which quickly become covered with a whitish mould. This product is the natural food of the young ant. The youngest larvæ live on the mould alone while the larger larvæ and adults consume both the mould and the fecal cakes, which by the way have been softened by the secretions of the superjacent fungus. Other specimens of the ant tribe cultivate these moulds for nutritive purposes. The "queen" on the occasion of a migration carries with her a specimen of the sacred fire, so to speak, to light a blaze at the new hearthstone; in more prosaic language she bears with her a specimen of ferment intended to be used in simple culture, not to ferment other food bodies. Nowhere else in Portier's opinion do we find an animal employing systematically a microorganism to prepare its nutriment. Mankind of course has used substances like beer wort and rennet and other ferment for milk products from the earliest times. To go from the ant to the caterpillar is to advance in constructive symbiosis, for these forms of the latter which feed on wood exhibit an intestinal content in which fungi are plainly seen to flourish on the digesting wood pulp. These organisms belong to the *Conidia* and while many of the spores are destroyed in the adult by phagocytosis others persist in the organism and entering the ova are transmitted to the next generation. The larva is thereby provided with its proper nutriment in advance. This is known as hereditary symbiosis. Apparently the wood-eating insects consume wood only as nutriment for the fungi which use it as a culture medium; and while the ant voids the combination of wood pulp and fungi for the next generation the larvæ of the butterfly and moth conserve the association within the organism so that the fungi abide in the ova as prenatal nutriment. Portier seeks to trace this principle up through the evolutionary scale and to explain by it many phenomena of human biology.

A Comparison of Breads.

Bread, the right kind of bread, is verily the staff of life, at any rate, for civilized peoples, and this fact has been accentuated by the necessities of war. Wheaten bread made from highly milled flour was for many years before the war the staple diet of practically all modern populations, who have by progressive pampering of their appetites developed extremely fastidious palates. For some considerable time, it has been pointed out that bread made from wheaten flour so dealt with that the portion of the grain in which the vitamine elements are present is got rid of, is not the kind of bread best adapted for the maintenance of health. By the elimination of the vitamine content, according to many investigators, conditions of disease are brought on. Not only does the absence of these essential elements of a diet predispose to or produce disease, but it is harmful from other points of view. In the first place, a bread or any food which requires little or no mastication is not good for the health. Such a diet does not give sufficient exercise for the teeth and jaws, nor for the digestive organs. It is believed by many, and with some apparent reason, that a main reason for the prevalence of constipation and dental caries among civilized communities is the habit of eating foods which are devoid of roughness and which call for little mastication. However, opinions as to the relative value of white flour bread and brown bread, or the lighter so-called 80 per cent. flour bread, vary. In the *Medical Press* of January 22, 1919, A. Stayt Dutton, discussing the matter of war bread, is inclined to depreciate the value of bread made from 80 per cent. flour and to extol white flour bread. He neglects, however, to mention that flour deprived of the germ and aleurone cells has been demonstrated to be unfitted to form the staple food of the population. The presence of the accessory or vitamine elements is essential for the proper nutrition of the nervous system and this alone is sufficient reason for the general use of bread in which the husk or part of the husk of the grain has been retained. So as to obtain the best results, bread should be made from a good quality of flour containing the germ and aleurone cells, and, above all, should be baked properly. A good deal of the prejudice against the so-called 80 per cent. wheaten flour bread is due to bad baking. When well baked it provides a sufficiently digestible and palatable bread, which contains the essential vitamines, affords exercise for the jaws and teeth, and work for the digestive functions.

Sublimate Kidneys.

Askanazy and Nakata have published an article on the stages of sublimate kidney in the *Correspondenz-Blatt für Schweizer Aerzte* for January 18, based on 15 cases of suicide from swallowing corrosive sublimate. Death took place at intervals which varied from 12 hours to 17 days. As all know, there is much discrepancy in the finds and criticism of the latter among pathologists in general. The authors claim that this discrepancy is due wholly to the failure to recognize the existence of three separate stages. These they denominate as follows: the red initial stage, the grey-white sublimate kidney, and the red sublimate kidney proper. The first may be

in evidence at any time during the first 24 hours. The organs are notably colored with an actual red or grayish red hue. The organ is hyperemic throughout but at the same time the degeneration of the renal epithelium may be already under way. This feature is now more fully developed and most fatal cases present it at autopsy. This second period stretches from the second to about the seventh day. The kidney loses completely any suggestion of red and becomes grey, either bluish or whitish grey. The microscope shows that the condition is in reality a pallor, the vessels having greatly reduced content. The anemia is due to compression by the tubules which are somewhat distended as a result of the degenerative process in the epithelia; in reality perhaps because of attempts at regeneration, new cells being in process of formation. The terminal red sublimate kidney is never seen before the first week following ingestion of the poison. It was present in seven of the author's series. The organ becomes once more light red or greyish red, which change is due to hyperemia and signifies the presence of active regeneration. The occluded tubules have in part expelled their contents while interstitial inflammation has taken place in some degree. Epithelial débris which cannot come away becomes calcified. As a result of their finds the authors dispute the word nephrosis in connection with sublimate kidney for they find everything which should be present in the makeup of a nephritis.

Acute Appendicitis in the Aged.

Dubs, in an article abstracted in *La Presse Médicale* for February 27, emphasizes the infrequency of this affection after the age of 50. In a material of 500 cases of the disease treated at a Swiss cantonal hospital during a period of three years only 19 occurred in subjects in the sixth decade, 4 in the seventh, and 2 in the eighth decade. In other words but 5 per cent. of these cases occur in subjects above 50 years. Figures show that at these advanced ages appendicitis occurs in two principal forms. The first is diffuse peritonitis following perforation and is fortunately rare, while in the other form the condition is of very slow evolution and may even simulate a neoplasm. Otherwise considered the attack in the elderly differs from the attack in the youthful because of the absence of a general reaction. The local symptoms may be sharply in evidence—notable muscular rigidity and marked tenderness to pressure, but reflex and constitutional symptoms are correspondingly less marked; for example nausea, which is usually absent. Whatever its intimate nature the treatment of appendicitis in the aged is essentially surgical and never expectant and the mortality under operation is about 12 per cent.

News of the Week.

Typhoid Epidemic in Baden.—A cablegram from Berlin to the *Associated Press* reports that an epidemic of typhoid fever is raging at Pforgheim, Baden. Thousands of persons are said to be stricken, and the epidemic is difficult to combat owing to the famished condition of the people.

Hospital Enlarges Site.—St. Vincent's Hospital, which has been gradually enlarging its site on the east side of Seventh Avenue, between Eleventh and Twelfth Streets, New York City, has recently added to its holdings a four-story dwelling fronting on West Eleventh Street.

Nutrition Inquiry in Germany.—According to an announcement from the State Department at Washington, a commission of physicians selected by representative organizations in neutral countries is about to inquire into existing nutrition conditions in Germany and Austria upon invitation from university faculties in Teutonic countries. It is reported that Norway has responded to the invitation, and that Dr. Brandt has left Christiania for Germany to serve on the commission.

Community Health Council.—At a meeting of the Community Health Councils for National Defense of New York City, on April 5, a Health Committee was organized under the chairmanship of Dr. Lee K. Frankel. The object of the organization is to undertake the establishment of preventive measures by bringing health questions clearly before the people. Dr. Frankel pointed out that following the influenza epidemic of 1891 there was an increased mortality rate for five years, and that the present epidemic would carry in its wake a similar increase unless vigorous measures were taken to safeguard the health of the people. In addition to a number of laymen interested in public health work the membership of the committee includes the following: Dr. S. Josephine Baker, Dr. John W. Brannan, Dr. Henry Dwight Chapin, Dr. S. S. Goldwater, Dr. Louis I. Harris, Dr. L. Emmett Holt, Dr. E. H. Lewinski-Corwin, Dr. Ralph Waldo Lobenstine, Dr. Frederick Peterson, Dr. Thomas A. Storey, Dr. Simon Tannenbaum, Dr. Herbert Wilcox, and Dr. Thomas D. Wood.

United States Interdepartmental Social Hygiene Board Announces Appropriations.—The United States Interdepartmental Social Hygiene Board, through its executive secretary, Dr. T. A. Storey, announces the following appropriations from the Scientific Research Fund of the Board: Leland Standford Junior University Medical School (1) for "Investigation into more effective treatment in acute and chronic gonorrhea," under the direction of Dr. R. L. Riglon and Dr. A. B. Spalding, $2,300; (2) for a study of "The Permeability of the Meninges to Antisyphilitic Drugs—An Attempt to Increase Their Permeability," under the direction of Dr. H. G. Mehrtens, $2,300; (3) for "Investigation Into More Effective Methods of Treating Syphilis," under the direction of Dr. H. E. Alderson, $2,600. The University of Michigan, College of Medicine and Surgery, has received an appropriation of $6,000 with which to conduct "A Research for an Improved Method of Demonstrating the *Spirochæta pallida* in Human Tissues," under the direction of Dr. A. S. Warthin. Regulations governing appropriations from this fund are published by the Government Printing Office stating the conditions under which the sum of $100,000 shall be paid to such universities, colleges, or other suitable institutions as in the judgment of the Social Hygiene Board are qualified for scientific research for the purpose of discovering more effective measures in the treatment and prevention of venereal diseases, copies of which may be obtained through the United States

Interdepartmental Social Hygiene Board, Washington, D. C.

United States Civil Service Examination for Medical Assistant.—The United States Civil Service Commission announces an open competitive examination for Medical Assistant, for men only, to fill a vacancy in the Bureau of Chemistry, Department of Agriculture, Washington, D. C., at a salary of $2,000 a year. Those qualifying will be eligible for future vacancies requiring similar qualifications. Applicants desiring to take this examination should apply for Form 2118, stating the title of the examination desired, to the United States Civil Service Commission, Washington, D. C., and applications properly executed should be filed with the Civil Service Commission prior to the hour of closing business on May 13, 1919.

Sir William Crookes, the famous chemist and physicist, whose experiments with vacuum tubes led the way to the discovery of the *x*-ray, died in London on April 4, at the age of 86 years. He also discovered the element thallium and was the inventor of the spinthariscope.

Medical Fees Under the Workmen's Compensation Laws.—At a recent meeting of the executive committee of the Physicians' Protective Association a resolution was passed calling attention to Governor Smith's message demanding revision of the Workman's Compensation Law, to prevent direct settlement between injured employees and the insurance carriers, and stating that a similar condition exists relating to the payment of physicians' fees by the insurance companies, which has resulted in the denial of the best medical service to the injured workmen and working women of the State. This is owing to the failure of the medical provisions of the Workman's Compensation Law either to provide a proper fee for medical service or to compel the payment of the fee awarded by the commission against the insurance companies. The Governor was asked to include in his proposed revision of the Workman's Compensation Law a measure to remedy this form of injustice to the medical profession.

Smallpox Epidemic in Italy.—A cable to the New York *Sun*, under date of March 31, reports a serious epidemic of smallpox, which for seven weeks has been ravaging the province of Apulia, Italy. It is said that thousands of the poorer classes have died, 1,500 having perished in the city of Bari alone.

Clinics for Treatment of Drug Addicts.—Frank Richardson, the head of the New York State Department of Narcotic Drug Control, has sent letters to Mayors and health officers throughout the State asking them immediately to take steps to establish local clinics for the treatment of drug addicts. He announces that a conference will be held on April 10 to speed up the work of checking sales of drugs. A plan is being prepared relative to the revocation of certificates of physicians who violate their authority to issue prescriptions for drugs. The commission will hold meetings in the several health zones of the State during April, May, and June to outline precautions necessary to prevent any undue use of drugs after prohibition goes into effect July 1. The New York City Health Department has opened a hospital for drug addicts on North Brother Island. The hospital has accommodations for 200 patients and will care for persons committed by the courts as well as those who voluntarily seek treatment.

Sanitation of Restaurant Kitchens.—Inspectors of the Bureau of Foods and Drugs of the New York Department of Health have been devoting attention to the methods employed in washing glasses and utensils used in restaurants, hotels, and ice cream parlors. Between October 8, 1918, and February 15, 1919, 196 arrests were made for violations, and of these 186 were fined a total of $904.

Dr. José Penna, a well-known internist, died suddenly in Buenos Aires, Argentina, on March 29.

Colonel Pearce Bailey of New York City, recently released from military duty, has been appointed medical chairman of the State Commission for Feebleminded to succeed Dr. Walter B. James resigned.

Dr. Royal S. Copeland, Health Commissioner of New York City, has issued a statement formally announcing his intention to resign his office in order to return to private practice.

Lieut.-Col. E. G. Zabriskie of New York City, has been designated senior consultant in neuropsychiatry for the American Expeditionary Forces, succeeding Col. Thomas W. Salmon, who has returned to the United States for duty in the Surgeon General's office. Dr. Zabriskie went to France as divisional neuropsychiatrist of the Fourth Division. Subsequently he was consultant in neuropsychiatry to the Third and Fifth Corps and to the First Army. After the armistice he served as consulting neuropsychiatrist to the Savenay Hospital Center.

Dr. B. J. Dreyfuss is conducting a Rectal Intestinal Clinic at the Harlem Dispensary, on Mondays, Wednesdays, and Fridays from 1.30 to 3.30 P. M.

Dr. David Bovaird, who has been serving in the Medical Corps of the United States Army, has resumed his medical practice at 32 East Sixty-fourth Street, New York City.

Obituary Notes.—Dr. DANIEL LEWIS, retired, a graduate of New York University Medical College, in 1871, died at his home in New York on March 22, aged 73 years.

Dr. EDWIN B. SHELTON, a graduate of Jefferson Medical College in 1889, died from Bright's disease at his home in Wickliffe, Ky., on March 19, aged 54 years.

Dr. RICHARD BROOKE MAURY of Memphis, Tenn., died from pneumonia at his residence in that city on March 17, aged 85 years. He was a graduate of the University of Virginia Medical School in 1858, a surgeon in the Confederate Army during the Civil War, being in charge of the Joseph E. Johnston Hospital for officers at Lauderdale Springs, Miss., as well as of other hospitals in that State and in Alabama. In 1867 he became professor of physiology in the Memphis Medical College, and a few years later became professor of the practice of medicine. In 1885 he assumed the chair of gynecology in the same institution. He served as president of the American Gynecological Society in 1906, and was also a member of the British Gynecological Society.

Dr. CHARLES FREDERICK DOLE, a graduate of Harvard Medical School in 1900, died after a long illness at his home in Sharon, Mass., on March 25, aged 43 years.

Dr. REMBERT TREZEVANT, a graduate of the Memphis (Tenn.) Medical College, in 1869, died at his

home in Evangeline, La., on March 15, aged 73 years.

Dr. JULIUS F. SIVENY of Auburn, Rhode Island, died in a New York hospital, following an operation, on March 16, aged 39 years.

Obituary.

FRANK VAN FLEET, M.D.

NEW YORK.

DR. FRANK VAN FLEET of New York died suddenly of heart disease in his office on March 5, aged 58 years. He was a graduate of Bellevue Hospital Medical College, in 1881, a former president of the Medical Society of the County of New York, and president of the Board of Surgeons of the Manhattan Eye, Ear, and Throat Hospital. He was consulting ophthalmologist to the Park Hospital and the House of the Good Shepherd. He was active in connection with the work on the draft boards and had served as consulting ophthalmologist to several government hospitals caring for wounded soldiers. He was a member of the New York Academy of Medicine, of the Medical Societies of the County and State of New York, and of the American Medical Association, and was a fellow of the American College of Surgeons. He is survived by a son who is a lieutenant in the Medical Corps of the U. S. Navy. For many years he was an active member of the legislative committee of the Medical Society of the County of New York and was instrumental in defeating many of the bills prejudicial to the health of the community and to the interests of the medical profession which are so constantly being prepared for adoption by the State Legislature.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, March 13, 1919.

The Cost of Medical Education.—The question of what, if any, pecuniary support should be given by the State to medical education has come into prominence again during the last week owing to the publication verbatim of the addresses of a group of distinguished men who recently urged upon the Government that in so many words higher education in England was still starving. The arguments put forward for State help in medical education were very forcible, and can be summarized much as follows:

1. The medical profession is in Great Britain on the whole poorly paid. It is true that since the institution of National Insurance there are more safe, if small, incomes to be made; but there is no progression by merit in this side of professional work; rather the tendency is that, the more a man obtains experience, the less will his income be. Further, there are no great pecuniary prizes in medicine that can be counted upon as a return for either industry or intellect, unless we except the gains of a small percentage of successful operating surgeons. Official posts, it is true, are getting more numerous, but compared with the salaries paid to State officers in the legal or the engineering professions, the emoluments and pension rates are meagre; there is no British medical man who gets an official salary more than half the size of the stipend of a Bishop of the Established Church, who moreover succeeds *in rota* to a seat in the House of Lords and as such becomes a legislator. On the whole the medical profession is poorly paid.

2. Yet this poorly paid profession exacts five or six years at least of strenuous work from those who would enter it, and the cost is expensive, not less than $5,000. The *Lancet* has estimated the figure as now being greater; and certainly it will become greater in the near future, for the mere material cost of medical education is advancing *pari passu* with the elaboration of scientific methods, the invention of new instruments, the introduction into clinical medicine and clinical surgery of a world of elaborate mechanism like that connected with radiology or with electrical treatment.

3. But this expensive profession is largely recruited from the sons of middle-class men who succeed to no private means, and whose parents are often sorely tried to find the money to support their children through a long and expensive curriculum.

4. Medical education, however, is controlled by the General Medical Council, a statutory body acting under the Privy Council, which has the duty of regulating the examinations by which medical students are admitted to the Medical Register. The work done by the Council in this as well as in other directions is delicate and arduous, *and it is carried on in the public behalf and in no sense for the protection of the profession of medicine.* The Council works under the Medical Acts, which are definitely designed to see that the medical profession is properly conducted and properly managed, so as to supply the public with adequate medical assistance. Yet this Council receives no grant from the Crown. The whole of its work is paid for by medical men who after their examinations proceed to registration by payment of a capitation fee. The income from these capitation fees supports the Council.

5. And while the Council, though existing for the public, is paid by the medical profession to see that the examination tests are good, the teachers, whose exertions bring the students up to the necessary mark, are either unpaid, or very poorly paid. Few of the medical schools, even those connected with wealthy universities, have any funds to be spent in a generous manner upon professorships, readerships, and lectureships in medical subjects; and much of the clinical instruction given in the wards by the staffs of the voluntary hospitals to their pupils is given gratuitously.

On these grounds medical men feel strongly that the time has come when an endeavor should be made to get from the Government some endowment of medical education commensurate with the value to the State of a well instructed medical profession. The Board of Education makes grants to certain medical schools, regarding them as institutions of technical instruction, but this is a drop in the bucket in comparison with the fluid cash that is required. The strong hope of the

medical profession is that in the debates in committee which will now follow upon the first reading of the Ministry of Health Bill, some of these questions will be thoroughly thrashed out. The position is not understood by the public and probably is but little better understood by the legislator. It would be very interesting if some American authority upon medical education would publish in England, at the present moment a succinct statement on the American position that it might be compared with the British position. How much does the medical training cost an American student, and how well- or ill-paid are his instructors, and who finds the money?

Death of a Famous Dentist.—Dr. George Cunningham, the well-known lecturer on dental anatomy and surgery of the mouth at Cambridge University has died at the age of 67 from respiratory troubles following influenza. An M.A. Cantab, he learned his science at Harvard, of which university he was a D.M.D., and first came into prominence in London as a member of the teaching and operative staff of the National Dental College and Hospital, and dental surgeon to the London Hospital. Later he migrated to Cambridge where he became not only well-known as a dental practitioner, but a strenuous and generous supporter of all movements in the cause of public health. I lay stress on the adjective "generous" because Cunningham neglected his private affairs for the public good in such a way as seriously to embarrass himself pecuniarily; few people knew that of him, until he was awarded a civil list pension, which might well have been larger, having regard to one piece only of his public work. He was appointed by the Home Office to report upon the use of phosphorus in the manufacture of lucifer matches, and his recommendations and opinions led immediately to the practical banishment of phosphorus necrosis from match factories. Cunningham was among the best known of British dentists away from his home country, being a member of numerous dental and odontological societies in the United States of America, France, Sweden and Holland, while at International Medical Congresses and Congresses of Hygiene, he frequently expounded the relation between sound teeth and good public health.

The Position of the Demobilized Practitioner.—A letter appeared this week in *The Times*, signed by Dr. Norman Moore, the president of the Royal College of Physicians of London, and Sir George Makins, the president of the Royal College of Surgeons of England, in which it was pointed out that certain of the conditions arising in the course of demobilization have not received sufficient attention from the authorities.

And it is a fact that the status and prospects of the medical practitioners who have been serving abroad have attracted slight consideration in spite of the activities of the Central Medical War Committee and of its Committee of Reference, formed from Dr. Moore's and Sir George Makins's Colleges. These statutory bodies made the best temporary arrangements which they could, to preserve, while the war was on, the interests of practitioners who had been called to the service of the country abroad. None the less, the future of many of these men is precarious, and the medical profession as a whole resents the fact that this should be.

The representations of the two presidents in *The Times* have been clearly designed to arouse the public conscience to the position. They point out that the medical men who have been working at home have generally behaved with the utmost fidelity to those who have been called away, and it is a fact that the majority of the medical men who remained in the country conformed to the various plans that were suggested for the maintenance of the interests of their colleagues abroad. Cases there have been where the man at home has not played so generous a part, but their number has been exaggerated, and, even when they have occurred, the fault has primarily lain with the public, who were quite unable to see that by exercising their right to a choice of doctor in too strict a manner, they might be severely injuring men who were fighting the cause of the country on foreign soils. The many difficulties attendant on dividing up practices, that have become conglomerated and whose personnels have changed in every manner, into anything like their original constituent parts, are obvious. During four and a half years of war many patients have died, and many have been born, while small neighborhoods have become very large, and large neighborhoods have shrunk. Houses are empty that were overfull; houses are sought for where no such accommodation exists; so that there is no return to an original pattern in correspondence with which a division of existing practices can be made in any strict manner. For these reasons it is obvious that the future position of the demobilized practitioner can only be ensured by a public comprehension of the conditions. Public bodies may be trusted to reinstate, as far as possible, to their former posts the medical officers who before the war held appointments in their service; but it is essential that the public should aid the demobilized practitioners by the promotion of a general feeling that their former patients should continue to call them in; and it may be pointed out that in most instances those who have served with the forces are returning with an enlarged experience, a broader outlook, and a more intimate knowledge of men and manners—qualities which are likely to be of great value to their patients.

Simultaneously Sir Robert Philip, president of the Royal College of Physicians of Edinburgh, and Mr. McKenzie Johnston, president of the analogous College of Physicians, drew attention in the medical press to the problems of demobilization as they affect the general practitioner of medicine, and they too ask for sympathetic consideration from the general public.

"Many doctors," they say, "who throughout the war have held commissions in the Navy, the Army, or the Air Force have now to face the question of return to civil practice. This is for them far from an easy matter. The natural growth of their practices has ceased during their absence. In spite of loyal help given, in most cases, by their colleagues—who deserve all thanks for their ungrudging efforts—and by professional committees, to hold together the practice in the interest of the

absentee, the normal wastage due to deaths, changes of residence, etc., has had the effect of materially reducing the practice from what it was in 1914. Beyond such unavoidable influences there is risk of curtailment from other causes."

The Scottish Presidents further make the good point that in a profession like medicine, where the work is essentially personal, the future of the demobilized medical men must depend on the attitude of the general public; and they would have the public interpret this personal feeling rather less narrowly than is expressed by the admitted right of the public to employ whatever doctor they choose. Where the personal relations of the patient to his medical man were, before the war, of the properly trustful and confidential sort, the patient should be ready—indeed, should feel it an honorable duty—to return to his old adviser whose absence from his practice has been at the call of the country. It is true that in the meantime similar pleasant relations may have arisen between the patient and the medical man acting in behalf of his absent brother; but while the substitute doctor is ready with all loyalty to hand over the patients to their former adviser, the delicate task of transference will be enormously simplified if the public acquires the feeling that such transference is right.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, March 3, 1919.

Death of Professor Chantemesse.—Professor André Chantemesse has just succumbed in Paris to an attack of grippe which laid him up a few days ago. He was in his sixty-eighth year, being born at La Puy (Haute-Loire) on October 13, 1851. He leaves a son who is an officer in the French Army. M. Chantemesse studied in Paris under Pasteur and Professor Cornil. He visited Germany and worked in the laboratories of Koch and Bollinger. In 1885 he was appointed physician of the Paris Hospitals and passed his "concours d'agrégation" brilliantly in 1889. The Faculté de Médecine then appointed him to the chair of experimental and comparative pathology, and soon after he was appointed professor of hygiene. He was made a member of the Académie de Médecine in 1901. He was a member of the Comité Consultatif d'Hygiène de France and of the Comité de Salubrité de la Seine and became Inspector-General of Sanitary Services. He was entrusted with numerous missions in France and abroad Professor Chantemesse's principal works were connected with bacteriology, epidemic dysentery, infection of water, and with typhoid fever, against which he discovered a serum. A recent article by Professor Chantemesse demonstrated that many epidemic diseases, and particularly cholera, may be transmitted by flies.

Death of Dr. Morestin.—Another great surgeon has just died and his loss will be irreparable. H. Morestin during the four years of war became celebrated as the greatest living plastic surgeon. All of the badly disfigured cases of gunshot or shell wounds were sent to him and he practically made new faces for all of this class of wounded. His energy seemed inexhaustible. He worked without ceasing. He had a service in Valle de Grace Hospital, St. Louis, and his own institution over which he presided, the Rothschild Hospital. From time to time he presented the results of his work before the Surgical Society and Academy of Medicine and moved his colleagues to wonder by the results he secured. He was a student of Verneuil and later of Richelot whom he succeeded at St. Louis when the former retired full of years and honors. In the immensity of his work for those mutilated by war he knew no rest. He worked rapidly, feverishly; brushing aside all minor difficulties and restraints, he went directly to the results he desired, so much so that he was called brutal in his methods. Thin, wiry, nervous, and quick, he appeared brusque and unsociable, but he accomplished a tremendous amount of work and despite fatigue and signs of strain he continued without ceasing to the last day of his strength, falling a victim to quick consumption at the age of 49.

Return of the Influenza.—Another illusion has been shattered by the prevailing outbreak of grippe. It was formerly thought that influenza rarely attacked a person twice. This idea has now been proved erroneous. According to statistics gathered by the *Matin*, about a third of those now suffering from grippe have had a previous attack quite recently. Instead of acquiring immunity, they would seem to have been rendered more susceptible to the malady. No precaution should be neglected, therefore, to avoid possible contagion, particularly in view of the virulence of the present epidemic. In England, the deaths attributed to influenza numbered 3,046 last week, as compared with the previous week's record, 1,363. Although the outbreak in Paris is less severe, the statistics of deaths from grippe show an upward tendency.

Among the preventive measures which have been tried in England, one of the most efficacious is the simplest. It consists of gargling frequently and douching the nostrils with a solution of a tablespoonful of common salt in a quart of tepid water. As regards treatment Professor Albert Robin recommends pyramidon and quinine hydrochloride to counteract fever and hot infusions to provoke perspiration.

7. Diabetes mellitus.—T. Webster Edgar is of opinion that the solution of the diabetic perception is to be found in the lower bowel. He points out that intestinal stasis has a direct bearing on the proportion of glycosuria cases and that from a therapeutic point of view the condition may be divided into four main groups: (1) cases in which the symptoms are physical signs and which yield readily to therapeutic measures; (2) cases in which the symptoms are more pronounced and accompanied by objective indications of an abnormal

state of the digestive tract, but which are amenable to medical treatment; (3) cases which present extra-intestinal objective and subjective symptoms, amenable to specific and prolonged medical treatment; and (4) cases in which the condition of the intestinal canal is so abnormal that therapeusis fails and surgical intervention becomes necessary or inevitable. He places all glycosuria patients in the third of these groups, and has treated twenty cases of definite diabetes successfully, accepting chronic intestinal stasis and toxemia as the predisposing etiological factor. In over 80 per cent. of his cases, Edgar has been able to elicit a history of intestinal stasis and intoxication of varying degree, extending back in people of middle age for from ten to twenty years, the constipation increasing as maturity approached. He is convinced that glycosuria is but one sequela or complication of chronic intestinal stasis and that the prodromal or incipient stage of diabetes mellitus is intestinal stasis and toxemia. Furthermore he believes that if prophylactic measures are instituted, the complication may be avoided, or obviated. Heredity plays its part by environment and association rather than by actually being a predisposing factor. Edgar has found that the assimilation limit for carbohydrate is greatly decreased in cases presenting symptoms of intestinal stasis and toxemia, even when the patient is aglycosuric. In such cases the blood pressure is correspondingly high. This prodromal condition was present in 90 per cent. of Edgar's cases and the average number of grams of sugar that any one of five preglycosuric cases could take care of without sugar appearing in the urine was in relation to the condition of the intestine and in direct proportion to the time the individual suffered from manifest symptoms of intestinal stasis. Putrefactive and fermentative processes in the lower bowel result in extensive multiplication of the normal habitat, usually the *Bacillus coli communis*, which under ordinary conditions is harmless, with retardation and destruction of local tissues together with inhibition and destruction of all tissue functioning with which the generated toxins come in contact. The colon bacillus is capable of producing absorbable toxins which act first on tissue proximal to the seat of generation, gradually causing an atonic condition of the nerve endings in the lower bowel. This process lowers the threshold of normal stimulation in the rectal nerves, defecation is interfered with and the individual becomes constipated, setting up a culture media acceptable to the growth and multiplication of the invading organism. This toxin is gradually absorbed by the lacteals and vessels, producing a degeneration throughout the entire body. The ductless glands by virtue of their peculiar nervous influence are the first to suffer, with resultant interference of their delicate mechanism and loss of ductless gland equilibrium. There is first an overproduction of secretion, then consequent retardation and a beginning degeneration; finally they become functionally inert. Thus a vicious circle is established, which first by its action on nervous tissue inhibits function, and then by increased production causes cessation of glandular activity. Edgar found that exercise had a direct bearing on sugar metabolism in cases of incipient or mild diabetes on normal diet, and especially on the percentage of sugar excreted in the urine when combined with intramuscular injections of diabetic serum, e.g., serum prepared from normal blood after the animal is exercised to the point of fatigue. He was able to increase considerably the carbohydrate tolerance by the injection of serum combined with treatment of lower bowel, but not with serum injection alone. The injections were withheld until the condition of the lower bowel responded to treatment, which was usually in from six to eight weeks. It would seem, therefore, that the musculature of the body is able to produce a carbolytic enzyme or sugar splitting body capable of taking care of the excess sugar in the blood, either by enzymotic or oxidative processes, the intramuscular injection of serum acting as an activating agent. No lasting result was obtained by muscle stimulation or exercise in diabetic patients themselves. The author attributes this to the facts that injection of a foreign serum produces an anaphylactic action which causes a revolution in the metabolic processes which cannot be produced by autoinoculation; and that the tolerance of the diabetic receptors being lowered they are not capable of receiving stimulation in the form of self-manufactured antibodies. He believes, therefore, that true diabetic glycosuria is due more to functional inability of the body to care for its carbohydrate content than an overproduction of sugar. He explains the action of the injections as follows: The muscles under stimulation and exercise produce paralactic or sacolactic acid, which is a product of fatigue. The glycogen in the muscles and excess sugar in the blood are destroyed by an amolytic enzyme activated by the injection of the serum, the glycogen being converted into sugar, lactic acid, and finally dioxide and water. In four cases Edgar has succeeded in causing the sugar to disappear entirely from the urine, the patients remaining aglycosuric up to the time of writing. The tolerance in all cases (20) is gradually increasing for carbohydrates and patients are gaining weight. He concludes by the statement that "diabetes mellitus is a sequel of chronic intestinal stasis."

5. Bacterial Protein Injections in Influenzal Pneumonia.—Dudley Roberts and Edward G. Cary report the results obtained in a series of cases of influenzal pneumonia treated by intravenous protein injections. This series was undertaken after the failure of other therapeutic methods, including blood transfusion from recovered patients and the hypodermic administration of mixed influenza, pneumococcus and streptococcus vaccines. At first it was thought that by the use of mixed influenza vaccines given intravenously a specific immunity might be quickly established against what were considered the secondary invaders, the pneumococci and streptococci. It was soon found, however, that in spite of massive consolidation, good results were obtained when there was a definite reaction following the injection and the authors therefore came to believe that the results were dependent upon a "nonspecific protein" reaction. They felt, however, that the use of a vaccine made from the prevalent organisms was advisable and no observations were made with other forms of protein. A saline suspension of heat killed organisms was used, so that each cubic centimeter contained 100 million influenza bacilli, 100 million pneumococci, types I, II, and III; 100 million streptococci and 100 million staphylococci. The initial dose used was 5 c.c. and this was doubled daily until four doses had been given. Later they used 1 c.c. as the initial dose and regulated the succeeding doses by the amount of reaction. Reaction occurred as a rule about half an hour after the injection in the form of a chill accompanied by definite rise in pulse rate. Half an hour to two hours later there was rise in temperature of from 1 to 3 degrees; this rise was of short duration and might easily be overlooked. When the chill is over and the temperature falls there is definite improvement in the condition of the patient. Generally speaking, the best results are obtained when there is a sharp reaction but this rule is not without exceptions. Two series of cases of definitely established pneumonias were chosen without regard to the condition of patient on admission to hospital; some in each series were hopeless from the beginning and died within a few hours. In Series I, treated with expectant treatment, out of a total of 86 cases there were 27 deaths, a mortality of 31.2 per cent. In Series II, treated with protein injections, out of a total of 200 cases there were 19 deaths, a mortality of 9.5 per cent. Whereas the temperature usually re-

turned to normal by lysis, in the first series crisis occurred in 20 per cent. of the cases, and in the second series in 26 per cent. The authors point out that not only was the mortality reduced by the therapeutic procedure described but the course of the disease was materially shortened. They state that the idea of using injections of bacteria and foreign proteins in the treatment of disease was forced on their attention by the excellent results reported from the use of typhoid vaccines intravenously in the treatment of typhoid fever, and by the fact that equally good results have followed injection of other organisms. The use of proteins has been exemplified principally in the treatment of arthritis by typhoid vaccines. Apparently something happens as a result of the reaction following protein injections. Gay and Claypole have called attention to the rise in the leucocyte count; in the authors' cases this rise was transitory and varied in its maximum, the increase being polymorphonuclear and at no time eosinophilic. Various observers have seemed to prove that there is a higher agglutinin and lysin production in animals subjected to high temperatures; others have shown that the opsonin and lysin content of human and animal serum is definitely raised after the therapeutic injection of foreign protein. The authors state that they themselves have observed the most striking results in the prompt recovery of patients when the amount given was so small that a passive immunity was out of consideration.

Hermann concludes that "the intravenous injection of foreign protein serves as a stimulus for the liberation of specific antibodies in animals in which the previously injected antigen was unable to cause such a liberation." In other words, while the therapeutic injection is nonspecific, the antibody response is specific. Experience shows that the repetition of phenomena excited by the invasion of pathogenic micro-organisms, or their accentuation during the course of a disease, is frequently followed by striking clinical results. Much remains to be done to determine the most desirable kind of protein and dosage but the authors emphasize the fact that, apart from the dangers attending intravenous medication, the procedure is harmless. Bacterial vaccines commend themselves because they are always available in safe and convenient form and there is no danger of anaphylactic sensitization. The authors conclude that in influenzal pneumonia protein injections have a very definite therapeutic value and they are inclined to believe that the procedure will eventually come to be accepted as useful in a wide variety of infectious diseases.

3. Notes on Detoxicated Vaccines.—David Thomson has conducted extensive researches on the removal of the endotoxins from the gonococcus and other organisms in order to procure non-toxic vaccines which could be injected in sufficiently large doses to develop a great amount of immunity. By a procedure which will be described in a detailed paper to be published almost immediately, he has succeeded in reducing the toxicity of most germs some 50 to 100 times, and whereas with ordinary gonococcal vaccine it was necessary to commence treatment with doses not exceeding 5 millions and gradually increase to a maximum of 250 millions, in acute cases it was found possible to administer 2500 millions of detoxicated vaccine of the same strains and increase the dosage to 10,000 millions. Doses even as large as this caused less toxic symptoms than small doses of the ordinary vaccine. To test the therapeutic value of detoxicated vaccine, three parallel series of complement fixation tests were carried out on gonococcal cases. Series A received no vaccine treatment and showed on the average three units of immunity acquired naturally in the course of the disease; series B, treated with ordinary gonococcal vaccine, showed an average of four to five units of immunity; series C, treated with large doses of detoxicated vaccine, showed an average of eight to twelve units of immunity. The therapeutic results obtained corresponded very markedly with the serological tests, the cases showing the highest degree of immunity recovering much more rapidly. The results of inoculation in normal individuals were then compared. It was found that in subjects who had never suffered from gonorrhea and who gave a complete negative complement fixation reaction, no complement deviating substances were developed in the serum after an injection of 100 millions of ordinary gonococcal vaccine, followed by 200 millions six days later, but that malaise and fever were produced. On the other hand, a dose of 5000 millions of detoxicated gonococcal vaccine induced the formation of sufficient antisubstances in the blood to give a double positive reaction, and a dose of 10,000 millions developed a triple positive reaction; moreover, the symptoms arising from the dose of 5000 millions were scarcely noticeable and no fever was induced. Experiments have also been carried out with detoxicated vaccines for the prevention and treatment of bronchial and nasal catarrh with very promising results. Thomson adds that the clinical evidence is increasingly convincing that the detoxication process will eventually revolutionize the whole subject of treatment by vaccines as well as that of preventive inoculation.

8. Prophylaxis in Influenza.—F. T. Marchant submits the results of experiments undertaken to determine the germicidal value of emanations from the essential oils. The surface of the agar in several plates was smeared with coli broth, covers were applied, and the plates inverted. A drop of oil was then placed in what was previously the lid, so that only the volatilised material came in contact with the inoculated agar above it. The plates were then incubated for 24 hours at 37 deg. C. Growth was present in the plates in which the following oils were used: Oil of aniseed, oil of cloves, oil of eucalyptus, menthol, camphor, alcohol. However, in those in which oil of cinnamon and cloves, alcoholic solution of aniseed, cloves, cinnamon, and formalin, or formalin alone was used there was no growth. From these findings it would appear that oil of cinnamon destroys, or at least inhibits, growth of the organism. This is also true of formalin. The germicidal power of formic aldehyde is generally recognized and in the form of compressed tablets it is in demand for throat infections. Marchant has found that the irritating effect of formalin can be masked by the addition of cinnamon, the resultant mixture being both pleasant and of greater germicidal effect than the formalin alone. The most satisfactory results are obtained by adding 120 drops of oil of cinnamon and 60 drops of formalin to an ounce of alcohol. If a few drops of this mixture be placed on a handkerchief the alcohol quickly evaporates, leaving a very pleasant odor with no appreciable irritation from the formalin. Tests were made of the germicidal action of this mixture in the way already indicated, two drops of the mixture being placed in four agar plates and a fifth being used as control. After 30 minutes' exposure to the action of the volatile oil no growth was found. Growth was present in the control. Further experiments showed the shortest time of effective exposure to be 10 minutes and that the cinnamon alone did not destroy the organism. In order to prove that the organism was destroyed after 10 minutes' exposure sterile broth was poured on to the agar in plate, which was then incubated at 37 deg. C. for 24 hours. The broth remained clear. Marchant infers that since the coli organism is destroyed by 10 minutes' exposure to an alcoholic solution of oil of cinnamon and formalin, the influenza organisms would also be destroyed and believes that this mixture applied liberally to handkerchiefs would prove a useful prophylactic measure. The emanations would permeate the whole of the respiratory tract and would therefore, Marchant says, reach distant parts into which an ordinary gargle or a throat lozenge could not possibly penetrate.

7. The Value of the "No Good" Malocclusion. Douglas H. Stewart.

3. Feeding the Sick Child.—L. J. Simonton thinks that too much importance has been given to the chemical side of the picture and not enough consideration given to the fact that we have in the case of the sick child either some underlying defect or perhaps "idiosyncrasy," and also to the fact that the fault lies not with the food, but rather the weakened powers of digestion as a result of a temporary upset from one cause or another. In the latter case it is foolish to try to decide whether fat, protein or sugar is at fault; the fault lies in the child's weakened condition. In order to get this digestion back to normal we need simply to weaken the food for a time, eliminate intestinal toxins and sterilize the bowel. If there is an idiosyncrasy to certain articles of food, Simonton prefers the term anaphylaxis to milk; for instance, use one of the proprietary foods containing dried milk, give vitamines in the form of orange on mashed potato, until the acute attack has subsided and bowel returns to normal, when such articles as two-minute egg, etc., may be added to the diet. Oftentimes these children, on return to normal, where no anaphylaxis exists, are then able to metabolize fresh cow's milk. The constitutional causes underlying ileocolitis, aside from anaphylaxis, are often scurvy and rachitis. In scurvy furnish vitamines. In rachitis lime in assimilable form should be administered. The object of the author is to render the bowel sterile and the routine procedure is to clean out the bowel with full tablespoonful of castor oil, followed with daily dose of tablespoonful of mineral oil. Give intestinal antiseptics; copper arsenate, 1/200 to 1/1000 gram every three hours will answer. To this may be added bismuth, to aid formation of sulphides in the stools, and a little digestive elixir if desired. As to deficiency lying in intestinal secretion, it is Simonton's belief that the "alexins" are responsible by their absence for primary anaphylaxis.

7. The Value of the "No Good" Malocclusion.—Douglas H. Stewart makes the malocclusion of teeth the subject of the article of his series of the value of the "No Good" articles. If the teeth do not close properly ill health is the result. If there was a space upon every history chart for malformations of the dome and upper jaw, then would doctors and dentists begin to realize how many, very many days of sickness may be forestalled by setting mastication right at the age of five years or thereabouts. These facts are well known, but of what use is that knowledge if it is to be shelved or passed over in silence? The ignoring of a basic fact like the great importance of the relation of a good mouth to bodily health in no way lessens the importance of the fact itself. Therefore, perhaps, one of the greatest benefits to mankind would follow from a public health service that insisted that every child of from five to seven years of age should have a mouth that is either in good working order or is put into condition. The great treatment for many diseases lies in forced or ample nutrition, but this nutrition at the developmental age of childhood depends more upon mastication than upon almost any other factor. A small amount of study would suffice to show that if the upper jaw is much distorted then every cavity in the head is also distorted, with the possible exception of the ear, the function of which is but too often ruined by a catarrhal process that never would have started were it not for the bad ventilation of adjoining cavities and their membranes. Why not consider malocclusion as much of a symptom as any symptom and by its removal render the removal of other symptoms possible? Is it because of this that a shut mouth and well chewed food are perhaps two of the greatest barriers to various forms of infectious diseases? Has it never occurred to anybody that the baby that is nursing with a well shaped mouth and feeding from a breast that occludes that mouth escapes a lot of things, including scarlet fever? And it may be readily discovered that the family with good teeth and well closed mouths are almost immune, as compared with a family of mouth breathers, who are usually found to be "calamity gatherers."

Berliner klinische Wochenschrift.

December 16, 1918.

Juvenile Arteriosclerosis.—O. Meyer studies several cases of arteriosclerosis in young men dying from the effects of this process and concludes, by the method of exclusion, that this is due to primary hypertension whose cause still remains to be discovered. This primary hypertension is the etiological factor of early arteriosclerosis. In all the cases of juvenile arteriosclerosis, Meyer says, there was a marked sclerosis of the kidneys.

Divers' Disease.—A. Bornstein describes disturbances complained of by divers when they suddenly reach a depth of a few yards. The difference of tension in the external media acting upon the body surface and the air contained in the trachea and bronchial tubes produces an intense congestion of the respiratory system, as well as an afflux of blood to the head, which is in relation to the air contained in the closed and rigid helmet.

Prostatic Syphilis.—Th. Cohn describes a chronic inflammatory affection of the prostate in a sixty-year-old subject, having a destructive tendency. The writer concludes that the lesion was syphilitic, although Wassermann was negative. Three injections of 45 centigrams each of neosalvarsan, followed by an Hg. treatment, resulted in a rapid improvement.

Münchener medizinische Wochenschrift.

December 10, 1918.

Studies on the Etiological Agent of Influenza.—A Binder and H. Prell describe with abundant detai groups of granulations which they were able to stain in histologic sections from subjects dying from influ enza. Each granule measured from 0.3 to 0.6 μ in diameter. The writers do not hesitate to offer thes granular bodies as the etiological agent of the grippe although they do not bring forward any culture o inoculation experiments to back up their statement However, they call this problematical organism *Ænigmoplasma influenzæ* Prell.

Examination of the Exanthema of Latent Typhu Fever and Malaria According to Weiss' Procedure o Observation of the Capillaries.—G. Zuelzer believe that he is able to recognize latent typhus fever by sim ply examining microscopically the cutaneous capil laries in the living. He thinks that the procedure ma thus have a considerable value from the viewpoint o epidemiology. He gives the differential characters o the exanthema of typhoid and typhus fever, illustrate by microphotographs. The cutaneous manifestation of malaria are also studied and illustrated by micro photographs.

The Fundamental Notions of Modern Science o Heredity.—H. W. Siemens formulates, in a paper i which clearness is the least conspicuous quality, th Mendelian laws of heredity. Riddled with neologism this theoretical contribution ends with a conclusio weighty in consequences, namely, that a race whos nationality falls is destined to disappear.

A Report on a Small Epidemic of Trichinosis.—V Eisenhardt has noted as symptoms of this affection marked lassitude, even attaining muscular impotenc a high temperature from the start accompanied b edema of the lids. Intestinal disturbances were les frequent. The writer has been able to verify the grea diagnostic value of eosinophilia (as high as 62 pe cent.), accompanied by an absolute polynucleosi Arterial hypotension was constant. Thymol in th dose of 50 centigrams, repeated every two or thre hours, appears to have given good therapeutic resul in Eisenhardt's hands.

Deutsche medizinische Wochenschrift.

December 12, 1918.

On Silver-Salvarsan.—F. Hahn appears to be in accord with other writers on the subject of silver-salvarsan. He attributes a remarkable efficacy to this product, as well as a great facility in its exhibition and an absence of any unfavorable effects. A total of sixty-eight patients received five hundred injections altogether; unsuccessful results were rare, although the subjects represented all types and stages of syphilis.

The Treatment of Tetanus by Injections of Antitoxin in the Lateral Ventricle.—Horneffer has injected antidiphtheritic serum in the lateral ventricles and under the dura-mater in two cases of tetanus. From 5 to 10 cc. were injected into the ventricle and from 10 to 20 cc. into the subdural space. In both cases an improvement was noted within twenty-four hours in one and and after several days in the second. At the time the injections were given the disease offered a distinctly bad prognosis.

Cardiac Diagnosis by Military Surgeons at the Front.—Dannehl maintains a somewhat personal opinion when he asserts, as he does, that soldiers with heart lesions, or those suspected of having cardiac lesions, should not be sent to special medical centers for expert examination. The danger of these special centers is the unfavorable psychic action on the men. Instead, the writer is of the opinion that the men should be placed under observation in camp from the viewpoint of their physical resistance as well as the cardiac compensation in relation to the existing lesions, etc.

The Psychology of Moral Insanity.—S. Kornfeld offers a series of psychological considerations which he believes he has derived from direct observation of cases. He reduces the syndrome of moral insanity to a primary fundamental deficiency, namely, a complete absence of the sense of fear. This deficiency of the psychological being brings about disturbances of a moral and affective nature, quite in contrast with the intellectual value, which is usually complete, in individuals afflicted with this mental process.

Gazette des Hôpitaux.

February 22, 1919.

Encephalitis Lethargica and Mumps Meningitis.—Grenet relates a case which occurred last June in a boy of fourteen years stricken in the midst of health with symptoms suggestive of meningitis. The parotids were swollen and tender and there was difficulty in opening the mouth. There was also a gingivitis. The diagnosis of meningitis complicating mumps was thought to be fully warranted. During the next few days the situation showed no marked change. There was some tendency to somnolence and lethargy, the boy remaining passive throughout. While the lumbar punctate was suggestive of meningitis there was a singular absence of headache and vomiting and in other ways the meningitis was atypical; and while the temperature, nuchal rigidity and Kernig gradually subsided, the boy did not improve in other respects and his somnolence and lethargy increased. Certain ocular pareses present from the first persisted. After a period during which it was becoming very difficult to nourish the patient, he rallied slightly and from that moment began very slowly to improve. Despite his youth and original good condition, slight bed sores had formed and healed. The lumbar punctate had become normal. After one month of illness the patient had regained control over his lips; he smiled and tried to speak, and in another day had regained his voice. The ophthalmoplegia still persisted. As the child entered the third month of his illness he was still unable to walk because of slight paresis of one leg, his voice was still unnatural and the eye movements still abnormal. By the sixth month he had nearly recovered, the only sequel of the disease being a taciturnity and lessened impetus to play. This case was quite isolated in the community and apparently the diagnosis originally made was not changed until attention had become focussed on lethargic encephalitis, whereupon a retrospective diagnosis of this affection was suggested. The multiple pareses of the facial muscles, which also extended to the larynx and extremities, and even the lumbar punctates were of the types seen in lethargic encephalitis. But what of the mild parotitis and the gingivitis? The patient had seven brothers and sisters and not one of these presented any symptoms of mumps, although such a highly diffusible affection, had it existed, must have spread to some extent, for not one of the seven children had had that malady. On the other hand, Netter, an authority on lethargic encephalitis, has reported that in some of his cases of the latter there was an initial sore mouth and swollen parotids, which should decide the entire question in favor of encephalitis.

Revue Médicale de la Suisse Romande.

February, 1919.

Defense Reactions in Pandemic Grippe.—Wanner alludes to the lack of defense by the economy which is the cause of the high mortality of the prevalent epidemic. Not only is defense reaction conspicuous by its absence, but therapeutically the profession has been unable to offer any substitute. An experienced clinician has said of grippe-pneumonia that once a patient contracts it he may survive or perish, but if he survive he owes nothing at all to treatment. Such fatalism, however, is dangerous, in that it leads to a let-alone policy and we must continue our search for a direct remedy. It is unfortunate that we cannot foresee the natural course of a given case of influenza and that we have nothing on which to base prognosis. This very peculiarity makes it almost impossible to state in a given case when a remedy has been of benefit. Statistics have taught us little, especially when the figures are low. Is it possible to divide grippe into types each with its own physiognomy and thus advance our knowledge? We can at least isolate several of the more deadly manifestations, for example, asphyxia, and let our knowledge accumulate. The facts are bizarre in the extreme. We saw much asphyxia in the summer, but not so much in the cold months. We have seen marked cyanosis associated with quiet, slow respiration, which may also be deep and sighing, and have been disappointed in finding no evidence of pneumonia. Subjectively there were oppression and burning under the sternum. The expectoration was frothy, red, and scanty. We know that in these cases there is congestion or edema of the lungs or perhaps capillary bronchitis. The slow, deep breathing is due simply to the need of forcing air into the alveoli. It is the breathing of the asthmatic or croupy child. Thus far we have been unable to add to this defense by the economy. The phenomenon of congestion is practically universal and betrayed by red face, hemorrhages from the various mucosae—for not only the respiratory, but the other functional systems are affected. It is a defensive phenomenon, but since it tends to cyanosis and asphyxia is often inefficacious. We have but one dependable remedy to ward off the latter and that is venesection. The immediate results are at least often strikingly good. Perhaps more important still is the toxic element present, which gives rise to many manifestations, because it attacks all the organs. In the blood we have leucopenia and without leucocytes in the blood in sufficient amount resolution of a pneumonia cannot take place. Certain principles which cause leucocytosis in health have been found of no value in grippe. An exception may be the fixation abscess used freely by Revilliod. Two cases are cited in which turpentine was used for this purpose and apparently with success, but the author fails to give the blood counts before and after. In both cases electrargol was also used, although when employed without the fixation abscess it seems to have been inert. Turpentine may be a source of danger, for it must be eliminated by the kidneys, but those who have used it in hundreds of cases have never seen accidents of this sort. In theory there may be other dangers, as infection, sloughing, etc. To sum up, the author would assist nature's defense by producing a leucocytosis by means of an early injection of electrargol and the establishment of a fixation abscess. This measure would deal effectually with the toxic element.

Book Reviews.

THE SURGICAL CLINICS OF CHICAGO. Vol. II, No. 4, August, 1918. Octavo of 204 pages with 110 illustrations. Published bi-monthly. Price per year, $10.00. Philadelphia and London: W. B. Saunders Company, 1918.

THIS number of the Clinics contains much less than the average of really interesting and important material. In fact, it strikes the reviewer as something akin to a combination of odds and ends sufficient to fill the required number of pages. There are thirteen contributors (an unlucky number quite suitable for this volume) and several of them are making their initial contribution to this series of volumes. Among the most instructive articles are McArthur's clinic on "Tumor of the Pituitary Gland," with description and illustrations of operative technique; Bevan's clinical lecture on a case of "Hemangioma of the Scalp"; Eisendrath's lecture on "The Acute Abdomen," covering conditions of the upper abdomen, those of the lower abdomen to be discussed in the next issue of the Clinics; Schmidt's clinical lectures on "Operative Treatment of Urethral Fistula" and "Technical Errors in the Operative Treatment of Urethral Stricture," and Hessert's clinical lecture on "Fractures."

LES PROJECTILES INCLUS DANS LE MÉDIASTIN. Par RENÉ LE FORT, Professeur adjoint à la Faculté de Médecine de Lille, etc. Prix, 11 francs. Paris: Felix Alcan, 1918.

THIS volume is devoted necessarily to radiographic diagnosis and is illustrated with seventy-five radiographs. The book is not entirely a product of the war for some of the material goes back as far as 1900. The actual number of military cases is thirty-nine, to which are added several cases of juxtamediastinal lesions and the antebellum material, both of the latter classes being very light. Thirty-two of the war cases were subjected to operation and recovered, while but two patients were lost. Prognosis after this sort of lesion has not yet been formulated. It was once understood that operation should not be practised unless the patient seemed in danger. The author's complete investigation of the physiology and pathology of the subject with his operative results have made intervention relatively benign. Operation must be performed under intermittent control by the screen, electro-vibrator, and other resources now in use. The type of operation depends on circumstances, but wide transpleural incisions give the best illumination and operating space.

LEÇONS DE CHIRURGIE DE GUERRE. Publiées sous la direction de CL. REGAUD, Professor à l'Institut Pasteur, etc. Prix, 9 francs. Paris: Masson et Cie., 1918.

THIS volume is the product of the collaboration of thirteen of the instructors of the Centre d'Etudes et d'Enseignement Médico-Chirurgicale. In civil practice the names are all famous, including those of Leriche, Jeanbrau, Guillain, Lecene, Nogier, Tissier, and others of equal prominence. The work should therefore possess unusual advantages. Tissier deals with bacteriology, Jeanbrau with blood transfusion, Nogier with radioscopy, Leriche with fractures and injuries of joints, Lecene with cranial wounds, and elsewhere with tetanus, Guillain with injuries of the encephalon. A feature of the work is the fact that these eminent men were all civilians before the war. No strictly military surgeons are concerned in the personnel. The selection of the men is due evidently to their experience as teachers and writers on surgery, medicine, etc.

AMBULANCE DE L'OCEAN (LA PANNE). Tome VI, Fasc. I, July, 1918. Travaux publiés sous la Direction de Dr. A. DEPAGE. Secrétaires de la Rédaction Dr. A. P. DUSTIN et Dr. G. DEBAISIEUX. Prix, 18 francs. Paris: Masson et Cie., 1918.

THE present number of this serial publication contains thirteen articles, of which eight have to do directly with ordinary war wounds. Lesions of the joints and abdomen are each the subject of an extended chapter. Other themes considered are cramoplasty, tetanus, elimination of microorganisms which have been injected into the circulation, pleurisy with cholesterin crystals in the exudate, and the fasciculation of the nerves. The number contains 352 pages and is richly illustrated. Seldom do we encounter such a number and variety of pictures, diagrams, and charts.

THE ORTHOPEDIC TREATMENT OF GUNSHOT INJURIES. By LEO MAYER, A.M., M.D., Instructor in Orthopedic Surgery, New York Post-Graduate Medical School and Hospital. With an Introduction by Col. E. G. BRACKETT, M.C.N.A., Director of Military Orthopedic Surgery. Price, $2.50 net. Philadelphia and London: W. B. Saunders Company, 1918.

THIS book is devoted almost exclusively to the orthopedic features of treating gunshot injuries; but, as Mayer points out, there is no sharp dividing line between what the general surgeon and the orthopedist should handle, each necessarily doing more or less of the work that might be considered to belong to the other's specialty. After a short introduction, the book is divided into two parts: Part I covering work at the front, Part II that at base hospitals. In Part I there are four chapters: Fractures and Injuries to Joints; Injuries to Nerves; Injuries to the Muscles, Tendons, and Cutaneous Tissues; and Transportation of the Wounded. Fractures and joint injuries are briefly considered and the proper fixation apparatus indicated in more or less of a general way. In the chapter on nerve injuries the symptoms of injury to the principal peripheral nerves are given somewhat in detail, for Mayer considers the neurological examination important even at the front, since he thinks the treatment of nerve injuries should begin as soon as the patient reaches medical hands, and proper splinting is as essential for the injured nerves as for the fractured bone. The immediate treatment of nerve injuries is then outlined. In the treatment of injuries to muscles, tendons, and cutaneous tissues two principles must be followed: (1) prevent contractures; (2) seek to maintain function of the injured structures. The two pages on transportation of the wounded are largely taken up by illustrations and are very unsatisfactory. Even in peace times the problem of transportation of the wounded, by gunshot and other traumatic agents, is always with us and should have been dealt with somewhat in detail if at all.

Part II, occupying about three-fourths of the book, is divided into the following chapters: The Treatment of Bone Injuries; Joint Injuries; Contractures; The Treatment of Nerve Injuries; Injuries to Tendons and Tendon Operations; and Treatment of the Amputated. There is also a final chapter on The Aims and Organization of the Orthopedic Reconstruction Hospital. In the treatment of bone injuries non-operative methods of restoring continuity and correcting angulation are first taken up, then the operative, this latter applying especially to the cases of vicious and nonunion, Albee's operations being recommended for this class of cases. The treatment of joint injuries is pointed out under varying conditions, such as with and without infection, ankylosis, etc. The proper methods of handling contractures in various regions are briefly discussed. The question as to when to operate on nerve injuries is still *sub judice*. Mayer has formulated the following rules: "(1) When the symptoms of a nerve lesion are progressive, operate at once. . . . (2) If the symptoms are regressive, do not operate. . . . (3) In other cases, where there is no change whatever in the extent of the paralysis or of the sensory symptoms, wait until the wound has healed, and then determine on the basis of the anatomical course of the nerve and the direction of the bullet whether there is a strong probability that the nerve was directly injured by the passage of the projectile. If so, operate; if not, wait still longer." The technique of operation on the various peripheral motor nerves and tendons is given at considerable length. The chapter on the treatment of the amputated is very interesting, not only because of the technical points presented, but also through the discussion of apparatus for the upper and lower extremities and the development of prosthetic appliances so that the patient can work at various trades.

The book contains much information of value to those who have to do with reconstruction work. It is particularly strong on the symptomatology, diagnosis, and treatment of nerve injuries and on the technique of tendon operations.

Society Reports.

INTERNATIONAL CONFERENCE ON REHABILITATION OF THE DISABLED.

(*Concluded from page* 588.)

SEVERAL important and instructive papers were read concerning medical service in relation to rehabilitation.

Lieut.-Col. F. MCKELVEY BELL, Director of Medical Service, Department of Soldiers' Civil Reestablishment, Canada, discussed medical services for discharged Canadian soldiers. Colonel Bell described somewhat exhaustively the methods in vogue in Canada, from the medical point of view, for dealing with discharged soldiers in Canada. He said that the measures employed had met with a great deal of success, inasmuch as the majority of these men improved under treatment. The figures were very satisfactory; 64 per cent. either recovered or improved in sanatoriums. Tuberculosis is the disease from which they mainly suffer. Bell suggested that colonies be established for those who cannot do continuous labor, and that industrial colonies should be founded for feeble-minded epileptics and for sufferers from such types of mental disabilities. He was of the opinion that occupational therapy and its intelligent practice has been and is responsible for keeping down disease among returned soldiers. Out of 500,000 Canadians who served under the British flag there were only 100 incurable cases. In Canada it matters not whether the disabilities of a soldier have been incurred directly from the war or indirectly, all are treated and looked after medically and surgically. After a man has been medically examined and passed as fit it is considered that the Government is responsible for his welfare, so far as medical service is concerned. All ex-soldiers for one year after discharge are given medical treatment, whether the injuries or diseases occurred or were contracted while they were still in the army or not. Bell spoke in the very highest terms of the benefits derived from the employment of occupational therapy.

Dr. G. W. GRAHAM, Vocational Medical Adviser for Ontario, Department of Soldiers' Civil Reestablishment, Canada, dealt with the sphere of the medical adviser in Canada. He especially dealt upon the fact that the vocational officer must be endowed with tact and sympathy, as without the employment of these attributes his services will be bereft of much of their value. Also, and this is an essential point, the vocational officer must use great discretion in putting men to a retraining regimen; that is, he must be able to select or advise the man to undertake retraining for that trade or handicraft which is best suited to him. In order to be able to do this satisfactorily the vocational officer must be a good judge of character, and likewise must possess a considerable knowledge of the various trades and handicrafts. It must be borne in mind that the future success of the retrained man depends very largely upon the vocational officer. The pre-war occupation of a man must be taken into account. Before a final decision is come to as to the choice of a trade or handicraft the soldier should be referred to a specialist, so that as little room is left as possible for error as to choice of vocation.

Dr. DONALD A. KINGSTON, Vocational Medical Adviser for Montreal, Department of Soldiers' Civil Reestablishment, Canada, pointed out that frequently diagnosis of a man's disability is extremely difficult. A man may be suffering from a hidden disability which will tax the knowledge and skill of the medical advisor to the utmost to discover. Also Kingston drew attention to the fact that the war changed the mental attitude of a man profoundly. Men of the age of forty or thereabouts return from the front old men. A man who has been often close to death views life from altogether another aspect than one who has never undergone such an experience. The one who has been "over the top" many times comes back in an indifferent state of mind. He is inclined to think that nothing matters much. In short, he has lost the perspective of the civilian and he will be long before he regains it, if ever he does wholly. In addition, the returned soldier is to some extent an irresponsible being. His not to make reply, his not to reason why, his but to do or die. In addition to not being master of his actions, he is so carefully looked after by officers when in the ranks and so cared for, even pampered, when sick, that he loses the independence that he used to possess when a civilian. All these points then must be taken into consideration by the vocational officer in dealing with the returned soldier and render it necessary that, in order to obtain the best results, the vocational officer must himself be possessed of special characteristics, of which the chief are tact, sympathy, and infinite patience.

Dr. C. B. FARRAR, Psychiatrist, Medical Branch, Department of Soldiers' Civil Reestablishment, Canada, gave an address on the rehabilitation of those having nervous and mental disabilities. Dr. Farrar criticised the vague manner in which the nervous affections are grouped. Of the chronic, obdurate, difficult cases of neurosis, these is an underlying condition which is fundamentally constitutional. Instead of regarding only the superficial symptoms of nervous disability, we should analyze the condition; it will then be found that not more than 50 per cent. of these are, strictly speaking, cases of neurosis. Many of them are borderland subjects, who were passed into the army when men were badly wanted and when rigid examination was somewhat neglected. They are cases of emotional instability, psychopathic inferiority, but not mentally defective. In the opinion of Farrar, cases of dementia precox among returned soldiers are more common than those of all the mental diseases put together. Neurosis of primary origin and dementia precox supply four-fifths of all types. Eligibility of subjects of nervous disabilities for vocational training is not very great; vocational training plays very little part in purely mental cases. Farrar stated, what is very true, that the entire question of mental invalidism has attention focussed on it now as never before. Treatment, too, is under criticism, and indeed views on the whole subject of mental invalidism are undergoing revision.

Dr. ANDRÉ TREVES of Rennes, France, gave a brief paper dealing with medical service in relation to rehabilitation in France. He said that the French Government provides all discharged soldiers with free medical treatment. Just as it has been decided to provide the disabled with prosthetic appliances for the duration of his life, so a sick or wounded veteran is entitled to demand from the State free hospital treatment when such treatment is necessitated by a wound or by disease contracted in service. For example, a man has a fistula develop in his old wound, or a fractured bone with or without grafts breaks again in the old place as a result of some injury, or a man has contracted malaria or tuberculosis in the army and has been pensioned for it and is overcome by the disease—all such cases are entitled to free treatment and hospitalization. In respect to whether a disease is attributable to the war or not, the pension law is very liberal. It admits a presumption in favor of the man and his right to a pension for every illness contracted after sixty days' service, and, of course, by this very fact a man is entitled to free treatment for the sickness which occasioned his discharge. Naturally, the right can only be claimed for the wounds or disease which rendered the man unfit for service and thereby caused his discharge. If a soldier disabled in the arm breaks a leg or becomes tuberculous, the State is in no way responsible.

Referring to the French Departmental Committees which are analogous to the Local War Pension Committees of Great Britain, Dr. Treves pointed out that these committees send to the mayors of all the communities in the department questionnaires which the mayors are expected to fill out by giving the name, address and disability of all the discharged soldiers in the commune. They are also asked to state in each case whether the man is working and whether he has need of medical treatment or of trade training. Inspectors who are chosen from wounded officers and are attached to the departmental office go through the communes to verify the reports submitted by the mayor, get into touch with the discharged soldiers, and look into their needs. They may organize lectures of propaganda for reeducation and give to those interested all useful information about admittance to a reeducational school. All discharged soldiers are entitled to attend a reeducational school without cost to themselves.

In the section devoted to a consideration of the rehabilitation of the tuberculous the question was discussed on March 20. The first paper read was by Captain J. Roddick Byers, Medical Superintendent, Laurentian Sanatorium, Ste. Agathe des Monts, Quebec, Canada. Occupational therapy was introduced by Captain Byers for tuberculous Canadian soldiers in 1916. At the beginning physical therapy, that is, mechanotherapy and so on, was by no means popular and 48 per cent. of the men refused such treatment. It was then decided that something must be done to render these methods popular and vocational therapy was given a trial. It has become so interesting that the men are especially keen about it and every kind of vocational therapy is followed almost with avidity, all the classes being constantly filled. The system is commenced whilst the patients are in bed by knitting and so on and the modes of employment become more strenuous as the strength of the disabled increases. All kinds of vocational occupation and reeducation are carried on, drawing, engineering, engraving, typewriting, carving, languages taught, agricultural work, gardening. The results have been eminently satisfactory. More than 900 soldiers have passed through the institution and of these only twenty-four have died. Before leaving the sanatorium the candidates for discharge are subjected to somewhat severe physical tests in order to show as far as possible whether they are in a good physical condition. Captain Byers' address was illustrated by a large number of pictures on the screen depicting the patients in the different stages of occupational therapy.

Mrs. Ethel Wood, Secretary Local War Pensions Committee, spoke of the problems of the tuberculous soldier in Great Britain. She said that the problem of tuberculosis in Great Britain has increased enormously since the commencement of the war. Mrs. Wood referred to the effect of tuberculosis on the mental attitude of the returned soldier, saying that his mind is tinged with bitterness and that he is very impatient of restraint. She also said that in London the men dislike intensely the open-air treatment. Of course, for the good of his family and the community it is necessary to isolate those who have the disease in an advanced stage. The author drew attention to the well-known fact that it is almost impossible to make those who have been treated and are sufficiently recovered to be discharged understand that they must take precautions when at home. The British War Pensions Committee has provided separate beds and sometimes separate rooms for certain cases. Mrs. Wood emphasized the point that the atmosphere of hospitals for the treatment of tuberculous soldiers in London is highly depressing.

Col. George E. Bushnell, Medical Corps, U. S. Army, retired, described the Surgeon General's program for the care of tuberculous soldiers. He said that tuberculosis has been practically eliminated from the American army in France; that large hospitals for the treatment of tuberculous soldiers have been established in different parts of the country; that in all about 7,500 beds for such cases have been provided. Statistics as to results have not yet been compiled and collated, but so far as can be judged up to the present time, the effects of treatment have been favorable. Colonel Bushnell did not appear to be quite so enthusiastic with respect to the beneficial results of exercise in tuberculosis as are some. He thought it was better to go too long in the direction of rest than to give exercise too soon. Moreover, decision as to these points must be left to the physician and not to the reconstruction officer. Also while undoubtedly the psychological influence of exercise and occupational therapy counts for much, it is not wise to exaggerate this importance. He pointed out that the tuberculous patient is notoriously untrustworthy in his statements respecting his condition. He is generally unduly optimistic and what he says concerning his feelings must be largely discounted.

Dr. Bayard Crane of Rutland, Mass., discussed vocational work for the tuberculous. He laid emphasis on the fact that there is a type of tuberculosis which lies between the acute cases and the incipient, a chronic fibroid infectious type. Persons suffering with this kind of tuberculosis are not prone to die quickly and yet in every way they are misfits hygienically, economically, and socially. These unfortunates should be given a chance both for their own sakes and for the sake of the community. Dr. Crane holds, and his belief has been successfully tested by experience, that such people are best adapted for life in an industrial sanatorium or colony. They should be given whatever work is best suited to them. In this way an industrial sanatorium or colony is of great service therapeutically and economically. Dr. Crane, therefore, suggested for returned soldiers and sailors afflicted with tuberculosis, and especially for those with disease of a chronic semi-active type, industrial and agricultural colonies.

Capt. Edwin A. Baker, M.C. (Croix de Guerre), Department of Soldiers' Reestablishment, himself blinded in the war, gave an address on the after-care of blinded soldiers of the Canadian forces. The address dealt principally with the evolution and development of the methods of reeducating the blinded in war at St. Dunstan's House, London, rendered possible by the munificence of Sir Arthur Pearson. All of the first blinded Canadian soldiers underwent training and retraining at St. Dunstan's House. A few reached Canada without training and are being trained at the Military School, Hart House, Toronto. The methods used there are the same as those employed at St. Dunstan's House.

Dr. André Treves read a paper dealing with agricultural readaptation of the disabled in France. Of these 60 or 70 per cent. were farmers. The disabled numbered considerably more than half a million, so that the problem in France of how, with a stationary birth rate and with deplorable lack of healthy adults, properly to till the land, is more difficult of solution by far than in the other Allied countries. Even before the war congestion in the French cities was beginning to attract attention and, of course, at the present time the conditions unfavorable to working on the land are greatly intensified. France needs all her farmers, however much they be crippled, and, therefore, the energies of her surgeons are mainly directed toward rendering crippled farmers fit to work on the land. As Dr. Treves pointed out, difficulties which are reduced to a minimum for amputations below the knee are carried to the other extreme for thigh amputations, particularly when the stump left is very short. Before they are allowed to commence work they are fitted with a temporary appliance with what is known as a farmer's shoe or sabot, made as nearly as possible to the shape of the normal foot. There is also a large, round end with a leather shoe to obviate sinking into the soft ground. The large, round end can be fastened to the appliance instead of the ordinary rubber covered one, or it can be made adaptable to the rubber one. Property owners, farmers or agricultural laborers usually go home while their permanent apparatus is being made, and it is found that nearly all work in the fields.

For a long time these men made little use of their second and permanent appliance, because they preferred the ordinary wooden leg, but some of those now see their mistake. The American leg with which they are supplied, with a large sabot interchangeable with the better looking foot and ankle, has a contrivance by which they can work on their knees if they so desire.

For men with arm amputations the difficulties appeared at first insurmountable. The greater number of those who were equipped with apparatus during the first year of the war were lost to agriculture. Nowadays, with the improvements that have been made these men can adapt themselves to work quicker even than those with disabled legs. The progress in this matter is due entirely to the improved apparatus. Dr. Treves described the vast improvements that have been devised in tools fitted to the artificial limbs, so that men disabled or crippled, by aid of one or other of these improved apparatus and tools, are enabled to do almost any kind of agricultural work.

The account given above of the International Conference on Rehabilitation mentions but a tithe of the papers read. Owing to the lack of space, only the papers and addresses referring to surgical and medical matters have been discussed and even a good many of these have necessarily been passed over.

The meeting was in a way epoch-making and, of course, was the largest of its kind and most international in character ever held in this country and in the world. Undoubtedly it has done much good. The great lesson learned from the papers and discussions is that physical therapy has a remarkable curative and remedial value, a value not as yet appreciated at its full worth. Whether occupational therapy is more beneficial than mechanotherapy is a moot point. Both methods possess obvious merits and it is probable that Dr. Tait McKenzie is correct in saying that both should be employed according to the discretion of the surgeon in charge. The lesson learned through the war with regard to apparatus and tools for the disabled reeducation, and so on will be of the greatest service in civil life.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held February 18, 1919.

DR. EDMUND P. SHELBY IN THE CHAIR.

Dr. EDMUND P. SHELBY, in introducing Dr. Shively, recalled that Dr. Henry L. Loomis made the first attempt to induce artificial pneumothorax at Bellevue Hospital, and with most disastrous results. It was thought at that time that the method held little promise of relief for the sufferer from advanced tuberculosis; however, during the last seven or eight years the method had come into more general use and was giving much better results than were at first expected. It was largely due to the efforts of Dr. Shively that artificial pneumothorax held the place it now occupied.

Treatment of Advanced Tuberculosis of the Lungs by Artificial Pneumothorax.—Dr. HENRY L. SHIVELY presented this paper, in which he said that in addition to the hygienic measures, which could usually be carried out in a well conducted sanatorium, there were, he believed, but two really important curative measures in the treatment of pulmonary tuberculosis. These were the administration of tuberculin in selected afebrile cases with good resistance who had not obtained an arrest of their disease by the ordinary hygienic methods, and artificial pneumothorax for certain far advanced cases. It was the one thing that was unusually successful in combating an otherwise hopeless condition. Anyone with even three-fourths of a lung functionally capable might get along fairly well through a long and useful life, and it was upon this fact that the treatment by induced pneumothorax was based. It had long been a matter of observation that pleural effusion might have a favorable effect upon a tuberculous lung. It was an interesting fact in the history of the method that one of the pioneers in the development of the pneumothorax treatment was the distinguished Chicago surgeon, Murphy, who, in 1898, advocated and practised pneumothorax. It was eminently fitting that a surgeon should have contributed to the development of the idea, for the treatment was founded on the old and well-known surgical principle of immobilization and rest for a diseased organ. The application of this method to a diseased lung was not so simple and easy as in the case of a diseased joint, but the principle was the same. As to the indications for and limitations of the operation, it was formerly, and was sometimes still, urged that the treatment should be used only for patients in whom the disease was practically confined to one lung. It was not often, however, that one saw advanced tuberculosis in which some evidence of the disease might not be detected in both lungs. Some of the most brilliant results of the pneumothorax treatment had been in patients having a considerable involvement of both lungs. Here, as in every case of tuberculosis, the treatment should be individualized and based upon a rational study of the patient by all the ordinary methods of examination, including *x*-ray plates and the fluoroscope when possible. Cases most suitable for collapse therapy were those which had been thoroughly tried out and had failed to respond to other methods of treatment, who had active and progressive disease or a cavity in the top of one lung, with the other lung relatively sound, who were febrile, and losing weight. After a few injections in this unfavorable type of tuberculous patient, the temperature might drop to normal, the cough and expectoration be reduced by one-half or more, and the morale of the patient completely changed. The results were often life-saving and astonishingly brilliant in hemorrhagic cases. As the writer's experience with the method had increased he felt that there were fewer contraindications to a trial of pneumothorax than we had hitherto believed. Obviously moribund and incurable cases were to be excluded, and one would hesitate to apply the treatment to cases with grave complications, such as diabetes, advanced nephritis, intestinal tuberculosis, organic disease of the heart, tuberculous kidneys, and perhaps severe tuberculous laryngitis. He felt sure that the patient, if not permanently relieved, was often made more comfortable and his life prolonged by the treatment. When a cavity was present in a lower lobe the case was less favorable for treatment. The complications seen and the rare accidents reported were so infrequent that they could not count as a factor in determining a trial of pneumothorax in suitable cases. In five out of fifty of his cases he had had a pleurisy with effusion, which was a frequent complication noted by all who had used the treatment extensively. Aside from a reduction in the amount of gas possible to introduce on account of the bulk of the fluid, this complication had never seemed of much importance. The site chosen for the introduction of the needle was determined by a careful physical exploration of the patient's chest, by percussion and the stethoscope, and also the fluoroscopic and *x*-ray plates. In a number of cases in which the patients were too ill to be removed to an *x*-ray laboratory for examination he had not hesitated to make use of the treatment without preliminary *x*-ray examination. Cavities, adhesions, and thickened pleura were to be sedulously avoided, and an effort made to select a spot where the percussion note and the breath and voice sounds approximated most closely to the normal. The flow of gas should never be attempted until the readings of the manometer tube, wide oscillations with negative pressure, indicated beyond the possibility of a doubt that one had entered the free pleural cavity. Dr. Shively said he had never been able to understand why some writers advised arbitrarily limiting the amount of gas to 200, 300, or 400 c.c.; if the patient took the gas well he saw no reason why all of the gas that could be introduced without harm to the patient might not be given at the initial treatment. Dyspnea, rapid heart action, or pain should cause the cessation of the flow of gas, irrespective of the amount introduced, which in all cases would depend upon the subjective symptoms and objective signs during the administration. After the first few treatments the patient should have a rest in bed and careful observation, but later in many cases the gas might be administered as a part of the office treatment. The gas was usually absorbed more rapidly at first than after a number of injections had been given. A number of different gases had been employed in peumothorax. In practice it had been found that sterile nitrogen, on account of its being less rapidly absorbed than other gases experimented with, was the one to be usually preferred. At the Loomis Sanatorium and several other institutions in favorable climatic situations, atmospheric filtered air had been used with success. The disadvantage of this was its more rapid absorption. During the past three years the writer had employed the pneumothorax treatment in fifty cases, all of them in the far advanced stage of the disease, not more than ten of which were without cavities of considerable size. In twelve of these cases very good permanent results were obtained. In six the effects of the treatment might be considered somewhat spectacular, as, for instance, one patient who received twenty injections, lost her fever, cough, expectoration, and bacilli, gained 56 pounds, and had been apparently well for a year and a half.

Dr. S. ADOLPHUS KNOPF said that although a great deal had been learned that night about artificial pneumothorax, he considered that it was still in the experimental stage. There was no doubt, however, about its being a valuable means to improve certain cases of advanced tuberculosis, and a great help in uncontrollable hemorrhage. In advanced cases the difficulty in employing artificial pneumothorax was getting into the pleural cavity. Most advanced cases of pulmonary tuberculosis had many pleuritic adhesions. It was important to bear this in mind and to tell the patient of

the possibility of failure before undertaking the operation of artificial pneumothorax, so that he might be prepared in case it was impossible to enter the pleural cavity.

Dr. FENTON B. Turck said he spoke because Dr. Murphy was his former chief at the time he was carrying out these experiments on artificial pneumothorax, and one of the first cases they had was an abscess of the lung which was cured by his method of treatment. After this came the development of the use of nitrogen in tuberculous cases, and it was based on the idea of bringing together two edges of a wound. Dr. Murphy's great work was to bring tissue together to produce rapid healing. The bringing together of wounded surfaces and immobilization was the conception Dr. Murphy held at that time. One other point to be considered in these cases of advanced tuberculosis was the ravage of the tissues, which was not so much due to the tuberculous infection as to the products of necrosed tissue, these products causing more rapid results than the infection itself. Therefore in this connection it should be remembered that we were dealing with the autolyzed products of the tissues themselves. Working on this theory, he had in many cases in which there was the phthisis habitus used an antitoxin made by injecting human lung tissue into a horse to produce a serum. All were familiar with the results of foreign protein injections in stimulating bodily resistance and the use of the lung tissue served to give the protein the additional value of specificity. There were problems which were of very great moment in medicine in connection with tissue autolysis, and among them was the relation of tuberculous infection to tissue destruction and the effect of artificial pneumothorax in limiting tissue autolysis.

Dr. ALFRED MEYER asked if he had understood Dr. Shively to say that he would exclude diabetics as unsuited for the artificial pneumothorax treatment. He had taken that point of view originally and had hesitated several times to perform pneumothorax on patients having diabetes, but he had had an experience at the Polyclinic Hospital that had led him to change his views on this point. He had performed pneumothorax on a patient with a high percentage of sugar and acetonuria, with a bilateral pulmonary involvement and hemoptyses with brilliant results. This patient lived some years afterward. The immediate results of artificial pneumothorax were a fall in the temperature and relief of hemoptyses. He knew that he had prolonged the life of other patients with diabetes complicating tuberculosis by pneumothorax, and these experiences had made him feel that we should not exclude diabetics with pulmonary tuberculosis from the possible benefits of pneumothorax. Dr. Meyer said he was glad Dr. Shively had mentioned the value of manometric readings. Forlanini had finally been won over to the importance of taking these readings. The fact that Dr. Shively had followed this rule was probably the main reason he had had so few disastrous results in applying the treatment.

Dr. SHIVELY, in closing the discussion, stated that as to the treatment of lung abscesses, not associated with tuberculosis, by artificial pneumothorax he could only say that his experience had been limited to tuberculosis cases, but in a review of the literature he had seen a number of brilliant results reported from the use of pneumothorax in non-tuberculous abscesses, and this was one of the fields in which the procedure was being extensively used. The reason he had not touched upon this point in his paper was because the subject was so large that it was difficult, indeed impossible, to cover that part of the subject related to tuberculosis in a brief paper. In reference to the use of pneumothorax in diabetics, he did not mean that it was to be absolutely excluded. Among his cases in which pneumothorax was used were some of intestinal tuberculosis and Bright's disease complicating the pulmonary tuberculosis, but the point he wished to make was that in such cases one should not expect to get as good results in uncomplicated advanced pulmonary tuberculosis.

Some Lessons of the War.—Dr. JAMES ALEXANDER MILLER, speaking informally, reviewed the situation as regards tuberculosis among European nations at war, going over the ground covered in a recent address before the New York Academy of Medicine. (See MEDICAL RECORD, Feb. 8, 1919, p. 255.) He emphasized the lessons drawn at that time, namely: (1) The experience of the army indicated that there was less hazard than supposed in hard physical exertion and exposure, as regarded the breakdown of resistance to tuberculosis, provided these conditions were combined with open-air life. (2) There was relatively infrequent development of pulmonary tuberculosis as the result of exposure to poisonous or irritating gases and of chest wounds. (3) Following the system developed in the American army of rapid and systematic chest examination in the elimination of tuberculosis suspects, large groups, especially industrial workers, could be detected early. (4) Food was an important factor in increasing mortality from tuberculosis, and the effects of long continued malnutrition were cumulative. (5) The tuberculosis situation in France and England and its analysis as an industrial condition among young women would indicate the importance of the place in economics of industrial hygiene. Systematic supervision of working conditions should go hand in hand with home supervision and sanitation of workers. (6) Two phases of the experience of the Tuberculosis Commission in France possessed value for adaptation to the general tuberculosis problem; they were the organization of educational propaganda and the training of health visitors for tuberculosis and child hygiene. (7) The last suggestion presented by the war was that of reeducation and vocational training for the tuberculous.

Dr. MAURICE FISHBERG said that this was the second or third time he has listened to Dr. Miller's experiences in France and he had learned more from him as regards certain etiological factors of tuberculosis than he had for many years before. When we entered the war a scare cry was spread as if tuberculosis were the main menace. But this country was very fortunate in selecting two rational men to handle the tuberculosis problem during the period of the war. Colonel Bushnell, whose admirable work in the army was known at present all over the world, at once allayed the apprehensions of the alarmists. The Red Cross was equally fortunate in sending Dr. Miller to France to handle the problem among the civilians in that country. At the beginning of the war we were in imminent danger of sending "literature" and sputum cups to the trenches, as was, in fact, suggested by one well-known writer. But Dr. Miller, as well as Colonel Bushnell, acted differently. In May, 1915, Dr. Fishberg stated that he read a paper before the Academy in which he pointed out that the menace of tuberculosis was negligible, and that in no war of which we had any historical record had tuberculosis been found to present an important problem. This point of view aroused considerable criticism. Now Dr. Miller's report about conditions in France fully bore out the speaker's contentions in 1915. In fact, it appeared from Dr. Miller's remarks that thus far the country had been called upon to care for several hundred cases of tuberculosis among an expeditionary army of over two million in France. The National Tuberculosis Association had prepared to care for several hundred thousand. A peculiar feature of the problem was that the slight increase of tuberculosis during the war had been noted among non-combatants, especially among women. It had also been noted in non-belligerent countries to the same extent as in warring countries, all of which went to show that it was not directly warfare that was responsible, but probably the increase in the cost of living all over the world. Dr. Fishberg spoke of the excellent work done by the selective draft boards, and pointed out that signs of slight pathological changes in the thoracic viscera did not always mean tuberculosis. Many ex-patients of sanitoriums had made excellent soldiers and in Europe it had been found that even positive sputum did not always mean that the subject was unfit for military service.

Dr. BRUNO S. HOROWITZ said he had listened to Dr. Miller with great interest because of his own work in the army service, which was that of Special Tuberculosis Examiner. He was gratified to hear that so few cases of tuberculosis had developed among the men sent to France, as it showed the success of the rapid three-minute examinations used in the army. It was

surprising how much could be accomplished in so brief a period of time, if the method developed by the Section of Tuberculosis under the direction of Colonel Bushnell were properly employed. The examiners were urged to make a diagnosis upon the physical findings, if possible without recourse to bacteriological examination or observation in a hospital ward.

Dr. MILLER said he did not wish to have any misapprehension in regard to the work he had done on the Commission. Dr. Livingston Farrand had had charge of the work and deserved a great deal of credit for the diplomatic way in which he had handled the situation, and it was only right that all should know that it was due to his successful leadership that they had been able to accomplish what they did. The Red Cross was to be congratulated in having secured Dr. Farrand's services as director of its peace public health program. The medical profession should help the Red Cross in the campaign it was about to undertake to the end that the best results might be attained.

Dr. KNOPF said the statement of Dr. Miller that there were now about 6000 tuberculous soldiers in this country was absolutely correct. In the *American Journal of Public Health* for February, 1919, the statement was made that there would be 13,000 tuberculous soldiers and sailors in this country by 1920, and because there were already 5000 cases of tuberculosis among the military population, the United States Public Health Service was demanding from Congress an appropriation of $26,000,000 with which to build a chain of tuberculosis hospitals all over the country. The sum of $10,000,000 has been requested immediately to care for existing ones. It was planned to erect these hospitals on Government property.

Prevention of Relapses in Cases of Arrested Tuberculosis Among Soldiers.—Dr. S. ADOLPHUS KNOPF presented this communication, in which he declared that we should be just as eager to cure thoroughly, carefully, and lastingly the unfortunate soldiers who had contracted tuberculosis in the performance of their duty, and to re-establish their earning capacity, as we were to cure and rehabilitate those wounded by shell or shock. He described the precautionary measures employed to prevent the entrance of tuberculosis into the army and said that in spite of these there was a certain number of soldiers who had returned or were returning to us invalidated because of tuberculosis. To provide for these men eight hospitals, with a capacity of 8000 patients, had been constructed and were now in operation. The Government had announced its intention of caring for tuberculous soldiers until they had recovered or had made as complete recovery as was to be expected. Relapses from tuberculosis in the civilian population, particularly among the working classes, presented a most difficult medical and economic problem, but when it affected the soldiers and sailors, young men between twenty and thirty-six years of age, representing the flower of the manhood of the nation, it was all the more serious a problem. In his paper on "Blinded Soldiers as Masseurs," read before the Conference on Rehabilitation of the Wounded, September 20, 1918, he had endeavored to throw out some suggestions as to the possible solution of this problem, and the present paper presented a somewhat more elaborate study of the various phases involved and a description of some therapeutic methods whereby it was hoped to reduce the number of relapses among tuberculous soldiers and sailors and if possible shorten the time necessary to attain a reasonable security against any recurrence of the old trouble. While absolving the sanatoria and health resorts from all blame, Dr. Knopf stated that there was no denying the fact that a great number of patients returned home with the label "arrested case," whose muscles were flabby from the prolonged rest cure on the reclining chair, and whose respiratory system had become indolent because they could not and should not breathe deeply while their lesions were active. Very often the excellent climatic conditions which prevailed in sanatoria and health resorts had tended to increase their sensitiveness to atmospheric changes and not heighten the resistance to the invasion of pneumococci and the minor respiratory infections, all of which tended to reawaken an arrested tuberculous lesion. . Add to these the disturbing factors of the toxins (fatigue poisons), produced by overworked flabby muscles, and one need not wonder at the frequent relapses. In some institutions hydrotherapy was employed and this, after all, was the best means to fortify the circulatory, cutaneous, and nervous system against atmospheric changes and the invasion of microorganisms through the respiratory system. The same things might be said of that important part of our armamentarium for the treatment of numerous diseases in modern as well as ancient medicine known as massage, and so sadly neglected by most of us in the management of our tuberculous cases. The writer quoted from other authorities to show that in holding this opinion he did not stand alone. In his hospital practice in the City of New York, where he had to deal almost exclusively with advanced cases of tuberculosis, massage was not feasible and but rarely indicated, and the same was true of hydrotherapy and respiratory therapy, but in convalescent patients and in those returning from sanatoria as arrested cases they had proved of greatest value. He had been able to teach massage to many of his pupils and nurses and where, for financial reasons, a patient could not employ a masseur he had succeeded in teaching a well member of the family how to apply the treatment. It was surprising to see how many men and women there were with a natural aptitude for this work. Physiotherapy, that was to say, a judicious combination and application of massage, cold water, and graded breathing exercises, seemed up to this date our only means to prevent relapses in arrested cases of pulmonary tuberculosis. It should be applied for a period of four to six weeks after the case had been pronounced arrested. Individualizing in the post-sanatorium treatment of course was as essential as in the sanatorium treatment proper. The post-sanatorium treatment was not in any way intended to do away with the contemplated program of teaching our tuberculous soldiers a variety of trades and occupations before they left the military hospitals, each adapted to the individual so that it would be conducive to the preservation of his health and helpful in re-establishing his earning capacity. All the objections which confronted us in applying massage in private practice in sanatoria or in civil hospitals, such as financial considerations, unwillingness of the patient to remain, scarcity of masseurs, or phthisiophobia on the part of the latter, need not enter into consideration when we were dealing with tuberculous soldiers. The writer had the assurance that a number of war-blinded soldiers would be trained as masseurs in the U. S. Base Hospital No. 7 for the Blind at Roland Park, Baltimore, which was under the direction of Lieutenant-Colonel Bordley. If this hospital should not be able to provide a sufficient number of masseurs for this tuberculosis work, there would be among our maimed heroes a number who had received injuries to the lower extremities and other types of injuries who could be trained as masseurs. In the final analysis of this work of preventing relapses in cases of arrested tuberculosis among our soldiers there would be an actual saving of thousands and thousands of dollars of pension money, restoring inestimable man power, and saving valuable human lives. Dr. Knopf then described in detail the character of massage to be employed, stating that four simple movements, namely friction, kneading, tapping, and stroking, sufficed for all practical purposes. The so-called movement cure could be added to the general massage and was not difficult to teach or apply. These joint manipulations consists in assistive, passive, and resistive movements of the extremities. Although helpful, they were hardly necessary in the average case of the recovered tuberculosis invalid. The effect of massage applied as described was to arouse dormant capillaries, increase the area and speed of the circulation, further absorption, and stimulate the vasomotor nerves, all of which were aids and not hindrances to the heart's action and to nutrition in general. Dr. Knopf described in detail the method of accustoming a tuberculous individual to the use of cold water, the important precaution in such cases being to avoid chilling the patient. To do this he had the patient stand in a tub of hot water and with a spongle apply water at a temperature of 85° to the body; as time went on the temperature was gradually lowered until the

subject could use water at a temperature of 40° or 45°, which was usually the temperature of water coming from the faucet. In the beginning the patient should return immediately after the bath to a warm bed. If, in spite of all precautions, he failed to react the cold baths must be discontinued. The plentiful ingestion of pure water, in preference to all other beverages, played an important part in the success obtained with the external application of cold water. Respiratory exercises should not be resorted to as long as there was activity in the chest, but in dealing with entirely arrested cases one need not fear any harmful effect from this part of their physiotherapy. Nevertheless, as was shown, breathing exercises should be graded and the chest not violently but gradually expanded. These exercises were described in detail and demonstrated. It might be asked if there was anything in our materia medica which could help in making our cured tuberculous invalids more resistant to relapses, and to this he could say that he knew of nothing which could conscientiously be recommended for that purpose that was better than the soluble lime preparations, such as the syrup of calcii lactophosphate with or without iron. When all the measures described had been applied for a number of weeks and the patient was considered as safe from relapses as the physician's skill and his own personal care and training could make him, there remained the necessity of selecting an occupation and environment for him which would tend to increase his chance of remaining well and he must be impressed with the importance of regulating his life in conformity with the hygienic principles that he had learned during his treatment.

Dr. Fenton B. Turck stated that Dr. Knopf's presentation showed that the etiology of tuberculosis was dependent more upon autolyzed tissue cells and that the tuberculosis was a secondary infection. It was well known that starvation promoted cell autolysis and it was also known that specific treatment with tuberculin had been shown to be of almost no value whatever, but if one removed the influence of stasis which was increasing the formation of polypeptids from necrosed cells he accomplished something in the way of improving the condition of the patient. All this was brought out in the paper and showed the direction in which we were traveling and that we were acquiring a new conception of disease, and that influenza, pneumonia, and tuberculosis were diseases not primarily due to a microorganism, but that the part played by the microorganism was that of a secondary invader, as Dr. Miller has just stated. Therefore, the problem in many diseased conditions was one of tissue autolysis and the toxins of tissue autolysis and this would have to be solved if we were to meet conditions as they existed. Dr. Turck congratulated Dr. Knopf on his application of physiotherapy and emphasized the importance and value of these too frequently neglected measures. A more careful application of these methods would yield much more gratifying results than chasing the "will o' the wisp" of antitoxins against microorganisms, since by these means of tissue antisera and physiotherapy we could reach and stimulate to activity those diseased tissues that could not be reached by other means.

Influenza in a Tuberculosis Sanatorium.—Dr. Alfred Meyer read this paper. (See page 592.)

Dr. Fishberg stated that he had had 136 patients at the Montefiore Home and had had an experience very similar to that of Dr. Meyer. Supplies had been very freely carried into the institutions and people had gone in and out. One day there was a first case of influenza and within two days in one ward with thirty patients there were eighteen or twenty with influenza. Our previous ideas in regard to influenza in tuberculous patients had not been borne out by experience during the recent epidemic. The former idea was that if influenza attacked a tuberculous patient that patient was doomed, but that was not true. The mortality of influenza among tuberculous patients was about 4 or 5 per cent. and that was not higher than the mortality among other classes of individuals without tuberculosis. If the tuberculous lesion was inactive the patient had the same chance of recovery as any other person. If the tuberculosis was active and the fever high, then influenza was liable to prove fatal, but he had not seen a case of inactive tuberculosis aggravated by an attack of influenza, and the presence of tuberculosis did not adversely affect the prognosis.

Dr. Meyer said he thought we should reserve our judgment as to the effect of influenza in reactivating tuberculosis until more time had elapsed.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

California State Board of Examiners.

Sacramento, October 22-25, 1918.

(*Concluded from page* 550.)

GENERAL MEDICINE.

(Answer ten questions only.)

1. A child three years old has urticaria. Discuss probable etiology and the procedure necessary to determine the same.
2. A woman 20 years of age shows nervousness, loss of weight, irregular menstruation, slight cough, increased sweating and tachycardia. Discuss the diagnosis.
3. What significance has a "plus minus" Wassermann? Discuss fully.
4. Discuss the main complications to be feared the first two years in the course of lues and means of recognizing the same.
5. What are the causes of "Salvarsan death"? Of thrombophlebitis after Salvarsan injection?
6. A man 18 years of age has nodular swelling of legs anteriorly, fever, generalized pains, irregular heart and a positive Wassermann. Discuss the differential diagnosis and treatment (briefly).
7. A man 30 years of age has bradycardia, evening temperature, constipation, occipital aching and epistaxis. Discuss the diagnosis and treatment (briefly).
8. A patient presents a chronic relapsing, inflamed sensitive buccal mucosa, asthenia, pale frothy stool and more or less diarrhea. Discuss probable diagnosis and prognosis.
9. Discuss the etiology and prognosis of pruritus ani.
10. Differentiate between Bright's disease and myxedema and discuss etiology.
11. A young woman has rapidly developing marked edema of one eyelid, nausea, vomiting and severe colic. Discuss diagnosis and prognosis.
12. A young child has sudden vomiting, high temperature, furred tongue and flushed face. Discuss possible diagnosis.

SURGERY.

(Answer ten questions only.)

1. Ununited fracture of femur of ten weeks' duration two inches below great trochanter, in a woman 60 years of age. Give pathology.
2. In question one give technique of operative treatment and post-operative care.
3. Discuss movable kidney.
4. Give technique of an acceptable operation for the fixation of a movable kidney.
5. Give technique of suprapubic prostatectomy including pre-operative measures and post-operative care.
6. Discuss surgical treatment of empyema.
7. Give indications for and technique of skin grafting. Give three useful methods.
8. Discuss nerve suture.
9. Give pathology of a bunion. Give technique of its surgical relief and after care.
10. Give pathology of hemorrhoids. Give two acceptable methods for cure by surgery.
11. Give post-operative management of a hemophiliac (bleeder).
12. Discuss post-operative ileus.

ANSWERS.

GENERAL MEDICINE.

1. *Urticaria* in a child is probably due to some digestive disturbance such as eating some particular kind of

food (as strawberries); or to some irritant such as stinging nettles, or insect bites; or to dentition or intestinal worms. The diagnosis is made by observing the lesions—wheals (and papules and sometimes vesicles). The wheals are pale in the center, with red margins, and are distinctly raised, so that they can be felt with the hand; they cause intense itching, which may interfere with the child's sleep.

2. The patient may have phthisis, goiter, anemia or chlorosis. In case of *phthisis*, other marks will be: deficient chest expansion, prolonged expiration, dullness or impaired resonance over apex of lung, fine moist rales at end of inspiration, general weakness, dyspnea, anorexia, slight fever. In case of *goiter*, there will be the enlargement of the thyroid gland, exophthalmos, and nervous symptoms. In *chlorosis*, the blood examination will show a diminished hemoglobin content. A slight loss of red cells, poikilocytosis, and a slight leucocytosis. *Pernicious anemia*, the blood examination will show a diminution in the number of red cells, a relative increase in the amount of hemoglobin, the presence of nucleated red cells, and variation in the size of the red cells.

3. A *plus-minus Wassermann* has no more significance than a single plus or a minus Wassermann. It is not diagnostic of syphilis. Some observers believe that it indicates a syphilitic hereditary taint. It may bet met with in persons who give no history or signs of syphilis; it is also present in cases of malignant growths.

4. "The *secondary stage* of syphilis consists of lesions of the skin (syphilides), mucous membranes (mucous patches), appendages of the skin (onychia, paronychia, alopecia), enlargement of the lymph glands in different parts of the body, neuralgic pains, inflammation and thickening of the periosteum, arthropathies, iritis (rarely other forms of eye disease), epididymitis, and interference with the general health (fever, anemia, disorders of digestion) and with the process of reproduction. Retinitis, choroiditis, affections of the acoustic nerve, and meningitis are being reported as secondary manifestations with increasing frequency, whether as the result of salvarsan treatment or more careful observation is a matter of dispute. . . . *Syphilides* generally appear in from six to seven weeks after the appearance of the chancre, occasionally earlier, and sometimes, notably when mercurial treatment has been administered from the beginning, not for several months. The secondary skin rashes (*syphilodermata*) may (1) ape any form of cutaneous eruption, but are always an imperfect counterfeit; they are (2) often apyretic, (3) slow in evolution, (4) non-inflammatory, (5) seldom itching or painful, (6) often of a ham or copper color, (7) apt to occur in circles or segments of circles, and (8) when affecting the extremities, most frequent on the flexor surfaces (which include the sole of the foot and the palm of the hand); (9) they tend to recover, and are (10) superficial, (11) profuse, (12) disseminated, (13) polymorphous, (14) symmetrical, and (15) desquamating. . . . The *mucous membranes* are affected somewhat like the skin. The sore throat of secondary syphilis consists of a reddening of the fauces or tonsils, which is sharply limited, reniform in shape, and often followed by ulceration, the ulcerated area being shallow with a grayish color and steep edges. *Mucous patches* are papules due to the overgrowth of papillæ, which, owing to the sodden condition of the epithelium, are white in color; they are circular or oval in outline, may progress to ulceration, originate a highly contagious discharge, and are commonly seen in the mouth and about the anus and genitals. *Condylomata* are large tubercles due to hypertrophy of papillæ; they look somewhat like warts, often appear in cauliflower-like masses, and occur most frequently about the anus and genitals. Eruptions or inflammations in the larynx produce syphilitic hoarseness, in the ears transient deafness. *Syphilitic alopecia* is usually detected at the time of the sore throat and skin eruptions. It may involve the head alone or the entire body. It occurs as a general thinning of the hair or in irregular patches. The skin is apt to be scaly. As the follicles are not destroyed, the hair is usually reproduced. The *nails* may be shed owing to inflammation of the matrix (*onychia*), or the skin around the base of the nail may be inflamed or ulcerated (*paronychia*). The *bones* in various regions may be the seat of fugitive pains, which are usually more severe at night (*osteocopic pains*). Nodes due to periostitis may form, especially on the skull, clavicle, and tibia. In the *joints* a symmetrical synovitis may be noticed. *Syphilitic iritis* makes its appearance in from three to six months after the chancre. It affects one eye at first, but is very apt to spread to the other. There are pain, impairment of vision, photophobia, lacrymation, a pericorneal zone of hyperemia, blurring of the pupil, often a change in color of the iris, and irregularity of the pupil, which is usually small and fails to react to atropine. *Syphilitic epididymitis* may occur late in the secondary period, and consists of gummatous nodules which are quickly dispersed by mixed treatment; it may affect one or both sides. *Syphilitic orchitis* (*syphilitic sarcocele*) is a diffuse sclerosis of the testicle itself and belongs to the tertiary period."—Stewart's *Surgery*.)

5. *Salvarsan death* may be due to: Faulty technique, embolism, sepsis, arsenic poisoning, decomposition of the salvarsan with formation of toxic substances, liberation of endotoxins from the killed microorganisms, anaphylaxis, idiosyncrasy; cardiac collapse, nephritis, or encephalitis.

Thrombophlebitis may be caused by local necrosis of the tissues, and also by the presence of the salvarsan in the blood.

6. The patient has syphilis, and syphilitic periostitis, or ostitis. In this condition the pain is of a boring character and is worse at night. There is not the high fever which would be found in a pyogenic infection; and a tuberculous lesion would be accompanied by signs of tuberculosis elsewhere. Acute rheumatism involves joints, and is accompanied by profuse sweats; it responds to treatment by salicylates.

Treatment of syphilitic ostitis: The general health must be attended to; good food and tonics are indicated; antisyphilitic remedies should be given; incision of the periosteum, with removal of the diseased part of the bone may be necessary.

7. The case may be one of arteriosclerosis, but no diagnosis can be made from the meager information given in the question. Treatment consists in proper mode of life (quiet, hygienic, with gentle exercise, plain food); potassium iodide is useful.

8. The case may be one of dysentery—probably bacillary; a microscopical examination of the feces will decide the matter, by finding either the entamœba hystolitica (amebic dysentery) or Shiga's bacillus (bacillary dysentery). The information given in the question is too meager to act as the basis of an exact diagonsis. The condition is probably chronic, with acute exacerbations.

9. *Pruritus ani. Etiology:* Piles, anal fistula and ulceration, threadworms, eczema, nephritis, gout, jaundice, constipation, alcoholism, opium, or tobacco habit. Sometimes it is a neurosis.

Prognosis is guardedly favorable. Sometimes it disappears on the removal of the cause; sometimes it does not. Division of the sensory nerves of the affected part has cured some cases.

10. *To differentiate between Bright's disease and myxedema:* In Bright's disease there will be found pallor and subcutaneous swelling; albumin and casts will probably be found in the urine. In *myxedema* the following symptoms will be found (which are not present in Bright's disease): The skin is thick, dry, indurated, and does not pit on pressure; there is loss of hair, subnormal temperature, decided physical weakness, and mental apathy with slowness of speech and thought.

Etiology of Bright's Disease.—*Acute nephritis:* "Cold and exposure, scarlatina, diphtheria, malaria, and other infectious diseases, traumatism to the back, pregnancy, and the persistent use of irritants, such as turpentine, cantharides, phosphorus, ginger, etc., are the most common causes. It may also be associated with certain skin diseases, extensive burns of the skin, and simple follicular tonsillitis. The affection is most frequent in childhood."

Chronic parenchymatous nephritis: "It rarely follows an acute attack; in the majority of cases it is subacute or chronic from the onset. It is a disease of young adults, especially males, and is seldom observed after forty years of age. Habitual exposure to cold

and wet, malaria, syphilis, alcoholic excesses, chronic mercurialism, lead poisoning, opium habit, protracted suppuration, phthisis, hepatic disorders, pregnancy, and some undetermined nervous condition are the principal causes."

Chronic interstitial nephritis: "The disease occurs usually in males from forty to sixty years of age. It may be primary, or secondary to chronic parenchymatous nephritis. Gout, chronic lead poisoning, syphilis, alcoholism, opium habit, chronic cystitis, chronic gonorrhea, long-continued worry, anxiety or grief, alterations in the renal ganglionic centers, hereditary influences, passive congestion from heart disease, and hepatic disorders are the principal causes."—(Hughes' *Practice of Medicine.*)

Etiology of myxedema: Atrophy or diminution in the functional capacity of the thyroid gland.

11. The case is probably one of *angioneurotic edema.* The condition is generally transitory, but is apt to recur. When the colic is very severe, the condition may (at first) be taken for appendicitis; but the absence of fever and pain or tenderness in the right iliac fossa rule out appendicitis. The prognosis is good for the recovery from the present attack, but recurrence is to be expected.

12. All the features mentioned are present at the onset of scarlet fever. In twenty-four hours the characteristic eruption should be manifest. The sudden vomiting is also present at the onset of many other febrile infections and is seen in meningitis. In the latter case examination of the cerebrospinal fluid will aid in the diagnosis. In none of the conditions just mentioned is the fever likely to be so high as it is in scarlet fever. In tonsillitis there is a very high fever, but the characteristic rash is absent.

SURGERY.

1. *Pathology of ununited fracture of shaft of femur:* "There are two groups, one containing most of the cases, in which the fragments are united end to end or laterally and more or less closely by fibrous tissue, and another, very rare, in which a distinct joint has formed between them. The varieties of the first form are very numerous, the variations depending upon the relative positions of the fragments, the extent of the preliminary rarefaction, the amount of fibrous tissue, and the presence or absence of a productive osteitis or partial ossification of the bond. In short, the process of repair in any of the widely different forms imposed upon it by the character of the fracture and the displacement may be arrested at any period or may be continued unevenly but still incompletely at different points. Thus the fragments may be in close apposition and united by a short firm bond with only slight motion between them, or they may overlap in such a way that the surfaces of fracture are not apposed and the union is only by the thickened interposed connective tissue; or the displaced end may be enlarged, with osteophytes extending into the fibrous bond and separate nodules of bone developed within it, needing only a slight additional ossification for complete bony union; or the effect of the preliminary rarefaction of one or both fragments may not have been corrected by subsequent ossification, and they remain soft and spongy, or atrophied and pointed, and even this process of rarefaction may be so exaggerated as to create as distinct a gap between the fragments as if a piece had been removed or even to transform the entire shaft of the bone into a fibrous cord. Of the second form, the creation of a joint between the fragments, only a few examples have been recorded. They show, in more or less complete and distored forms joints with a fibrous capsule embedding cartilaginous or bony nodules, a cavity containing a synovia-like liquid, and the ends of the fragments rounded, eburnated, usually enlarged, sometimes smooth and polished and sometimes covered with a fibrous or even a cartilaginous lining."—(Stimson's *Fractures and Dislocations.*)

2. *Operative treatment of ununited fracture:* "The greatest possible care must be exercised to observe the rules of asepsis. A general anesthetic having been given and the parts prepared as for other aseptic operations, a constrictor is applied well above the seat of fracture. The ends of the fragments are exposed and freed of all fibrous tissue covering them. The ends are now resected to an extent sufficient to expose the medullary cavity of the bones. The bones should be squarely sawed across, so that exact end-to-end apposition is secured. There is considerable difference of opinion as to the advisability of using wire or other means of fixation. If apposition seems to be maintained when the bones are held together before closing the wound, no suture or other apparatus is necessary. Great care is to be observed in applying a cast or splint to prevent any disturbance in the apposition. If there is the least tendency for a malposition to recur it is the safest plan to use some form of retention. Silver or bronze aluminum wire are the best nonabsorbable materials, and kangaroo tendon and chromicized catgut the best absorbable substances. In the case of the femur, wire is the best. In general, a single opening through the cortex into the medulla will suffice. When the ends of the bones are atrophied or a considerable interval exists, an osteoplastic flap can be made by detaching portions of the bone with the periosteum and wedging them in between the fragments."—(Keen's *Surgery.*)

3. *Movable kidney.*—"This is to be distinguished from *floating kidney;* in the latter condition, which is said to be always congenital, the kidney passes forward into the abdominal cavity and is completely surrounded by peritoneum, being attached to the posterior abdominal wall by a mesonephron. In movable kidney the organ is excessively mobile behind the peritoneum. Eighty per cent. occur in women, and the right kidney is involved in about the same proportion. It is most common between twenty and forty, but may be seen at any time of life. The adrenal gland remains in place, since it lies in a separate compartment of the perirenal fascia. The *causes* are conditions which render the abdominal walls flaccid, such as pregnancy, emaciation, removal of abdominal tumors, etc.; Glénard's disease; tight lacing; trauma; and conditions which increase the size or weight of the kidney. In many cases, however, no cause can be found, beyond the fact that the patient has a long and slender waist, and this bodily conformation is inherited, hence movable kidney may exist in several members of the same family. According to the *symptoms* the cases may be divided into four classes: (1) In most cases symptoms are absent. (2) In others there is dragging pain in the loin, with indigestion and nervousness. (3) In this class complications arise. If the ureter becomes kinked or twisted, there is transient hydronephrosis, with violent pain in the kidney and epigastrium, vomiting, collapse, and subsequently elevation of temperature and the discharge of a large quantity of urine (*Dietl's crisis*); if the pedicle becomes twisted gangrene of the kidney may ensue. Dragging on the duodenum or bile ducts may cause gastric and biliary disturbances and even jaundice, and the condition is not infrequently associated with chronic appendicitis or mucous colitis. Albuminuria, pyuria, and occasionally hematuria may occur, from congestion of the kidney or pyelitis. (4) In this group the prolapse is secondary to tuberculosis, tumor, hydronephrosis, or some similar malady, hence presents the same symptoms as the primary trouble. In all cases the symptoms are intensified by exercise or by lying on the sound side, and are usually relieved by lying on the back. The diagnosis is made by feeling the kidney descend below its normal level on deep inspiration. In the severer forms the hands can be approximated above the kidney, and in the worse cases the kidney may be found in the pelvis; percussion over the loin is said to give resonance, but the sign is fallacious. The *x*-ray may show the position of the kidney and reveal unsuspected conditions, *e.g.* a calculus."—(Stewart's *Surgery.*)

4. *Operation for the fixation of movable kidney:* An incision is made in the lumbar region outside the edge of the quadratus lumborum, downward and outward, from the twelfth rib; the muscles are separated; the fatty capsule is opened, the kidney is caught and pulled into the wound. The true capsule is incised along the convexity, and part of it stripped back; two or three stout chromic gut sutures are inserted deeply in the cortex and the reflected capsule, and penetrate the muscles on each side of the wound, where they are tied together, so as to close the wound and fix the kidney. Strips of gauze should be packed down to the kidney, for drainage, and also to encourage the formation of

adhesions. The operation is carried out with the patient laid face downward, the belly resting on a narrow air pillow (*Edebohl's*) to push the kidney up into its place.—(Buchanan's *Surgery.*)

5. *Suprapubic prostatectomy:* "If there is much cystitis, the bladder must be carefully prepared for a few days by keeping the patient in bed and washing it out with a mild antiseptic, or even possibly by draining it. At the time of operation it is again irrigated, and some 6 ounces or so of boric acid lotion left in it. The patient is placed in the Trendelenburg position, and the usual suprapubic incision made into the bladder. The vesical wall is by some anchored to the abdominal parietes by a deep silkworm gut stitch on either side, so that it shall not be unduly torn or displaced in the subsequent manipulations; this step is not essential, although the introduction of a silk sling through the bladder wall on either side is desirable. The portion of the prostate projecting into the bladder is now carefully examined and its removal commenced. The index and middle fingers of the left hand (which is covered with a sterilized indiarubber glove) are introduced into the rectum so as to steady and push forward the prostate. The right index finger tears through the mucous membrane behind the projecting median lobe or collar, thus passing between it and the displaced sphincter vesicæ. It will often be found an easy matter to pass the finger around the enlarged organ and enucleate it; the larger the prostate, the more easily this is effected; but when it is comparatively small and hard enucleation may be difficult. In this procedure the ejaculatory ducts are torn across, as also the vessels which enter and leave the gland on either side. The urethra is either removed entirely, or the lower portion of it is detached and left behind. The prostate when free in its sheath remains either in one mass, or not unfrequently separates into two halves which can be peeled off the urethra and removed separately from the bladder. This enucleation is attended by remarkably little bleeding in the majority of cases, and even when at all free it can be quickly restrained by irrigating the cavity and bladder with hot saline or boric acid solution through a catheter. A large rubber tube is passed into the bladder and stitched in the lower angle of the wound, the upper end of which is closed by deep sutures. The wound is covered with a few layers of cyanide gauze, and over this absorbent wool is placed in sufficient quantity to take up the urine secreted. Morphia is often needed to combat the pain and spasm that supervene, and it is advisably given as a suppository, or as a starch and laudanum enema. The subsequent treatment varies somewhat. Probably the best method is to dress the wound with gauze and wool, which are renewed every four or six hours as may be required. The amount of dressing required is large, and the expense is considerable. Some surgeons employ Irving's apparatus, a glass cap which fits closely over the wound, kept in place by elastic bands round the body, and draining into tubes which carry away the urine to a bottle between the legs. This appliance keeps the patient dry, and saves the expense of dressing, but it keeps the patient on his back, it presses on the wound and lower abdomen, and probably it hinders the healing process somewhat. The bladder is irrigated daily through the suprapubic incision, and blood and small sloughs will escape for some days. As soon as the suprapubic wound is protected by a layer of granulations, the tube should be withdrawn, and the urine allowed to escape or to collect in the bladder. A catheter is passed about the end of the first week, and the bladder washed out through it. The patient is allowed up in an armchair as soon as possible to avoid pulmonary complication. Not infrequently he will commence to pass urine naturally in about a fortnight or three weeks, and subsequently the function will be maintained in a normal fashion."—(Rose and Carless' *Surgery.*)

6. *Empyema:* "Treatment should be undertaken without delay. Aspiration seldom cures, but may be undertaken where the dyspnea is great, and an anesthetic given afterward for the excision of a piece of rib. Drainage is always necessary, and is best done by excising a portion of the fifth or sixth rib in the mid-axillary line. The patient should be allowed to come round quickly from the anesthetic, so that the coughing which occurs will expel the masses of coagulated lymph and help to expand the lung. A big drainage-tube is then inserted. Daily dressings are necessary, but irrigation of the cavity is seldom needed. If, because of delay in treatment, the cavity does not soon close, Estlander's operation, or some modification, must be performed. The wound must be enlarged and a number of ribs exposed and sufficient of them removed to convert the cavity into a pyramidal one, the base of which is the open wound. This is packed with gauze and allowed to heal from the bottom. If the operation has to be extensive, the flaps are allowed to fall back upon the granulating surface of the lung, and in these cases marked scoliosis and weakness of that side of the chest follow."—(*Aids to Surgery.*)

7. *Skin grafting is indicated* in cases of large healthy sores, ulcers, burns, various defects of eyelids, cheeks, nose etc.; also to cover the raw surface after excision of skin in lupus. *Three methods:* (1) *Reverdin's Method:* Small pieces of cuticle and cutis are cut off with scissors and divided into two or three smaller pieces. There are placed here and there on the granulating surface. The ulcer is covered with aseptic protective and dressings, and left undisturbed for four or five days. The grafts form islands, from which the epithelium spreads. (2) *Thiersch's Method:* All the granulations are scraped away. The surface is covered with protective, and pressure applied while the grafts are being cut, to stop the bleeding. The best knife to use is a medium-sized amputation knife. Thin shavings as large as possible are cut down to the tops of the papillæ. These are spread evenly over the raw surface, overlapping one another as well as the edges. The whole is covered with sterile protective and dressings, and left for five days. Antiseptics should be avoided, and only sterile saline solution used. (3) The whole thickness of the skin is sometimes used, either detached altogether or left with a pedicle, which is detached after a week or ten days.—(*Aids to Surgery.*)

8. *Nerve suture:* "The treatment of a divided nerve depends upon its size and function. If small and of slight importance, no special treatment is required; but any of the main nerves of the extremities must be dealt with at once by *primary nerve suture.* This is best accomplished by using a domestic sewing needle without cutting edges, or a fine Hagedorn needle, and the finest chromicized catgut; one or more stitches should pass through the nerve, and the rest merely through the sheath. Absolute asepsis is essential in order to obtain satisfactory results. It is most desirable that the nerve should be protected from the pressure of adhesions by wrapping it in gold-beater's skin or Cargile membrane. In wounds involving the nerves about the wrist the deep fascia should also be carefully sutured to prevent the formation of adhesions between the nerves and tendons to the skin, whereby subsequent mobility would be impaired. If the wound has been inflicted months before, and a bulb has formed, *secondary nerve suture* must be employed. The nerve is first exposed by a free incision through the cicatrix, the two ends identified and isolated, and the fibrous tissue of the bulb removed to a sufficient extent to expose healthy nerve fibrillæ; the divided ends are then brought together with as little tension as possible. To bridge the gap traction upon each end of the nerve may be employed to stretch it, and the limb subsequently placed in such a position as to relax the parts—*e.g.* the wrist flexed to a right angle, or the elbow bent (except when dealing with the ulnar nerve above the elbow, flexion of which increases the tension on the nerve). Resection of a segment of bone may be justifiable in certain cases to allow the divided ends to be approximated."—(Rose and Carless' *Surgery.*)

9. *Bunion:* "Probably as the result of ill-fitting shoes, the proximal phalanx of the great toe is thrust outward and is subluxated on its metatarsal bone—*hallux valgus.* Over the enlarged metatarsophalangeal joint a bursa forms, which by pressure becomes painful, and frequently becomes infected. Palliative treatment of the milder forms consists in relief of pressure and in proper shoes. The frequently accompanying (and causal) flat-foot requires attention. For the severer grades excision of the head of the metatarsal, or of part of it, will usually be necessary. If secondarily infected, the bursa must first be opened and drained. There-

after shoes built on proper lines must be worn, and perhaps a flat-foot brace in addition. Some operators transplant the extensor tendon of the great toe."—(*Reference Handbook of the Medical Sciences.*)

10. *Pathology of hemorrhoids:* "*External piles* are found at the margin of the anus, and are covered with skin. They consist of a small central vein in a varicose state, surrounded by a development of subcutaneous fibrocellular tissue, which latter is much more abundant than the vascular element; they practically consist of longitudinal folds of skin of dark brown color radiating from the anus, and superficial to the sphincter."

"*Internal piles* consist of dilated veins held together by a certain amount of connective tissue, and covered by mucous membrane. At first they are quite soft and compressible, and easily emptied on pressure; but when they have existed for some time the connective tissue may be increased in amount, and arterial twigs are often found running into the mass. The condition is limited to the lower two inches of the bowel, and may present very varied appearances in different cases. Thus, there may be general dilatation of the veins in the submucous tissue without the formation of any distinct tumors. The mucous membrane is then of a deep claret color, somewhat thickened, and liable to protrude during defecation.....When distinct hemorrhoidal masses form, they may be of two types: (*a*) The *longitudinal or fleshy pile,* consisting of broad sessile masses, dusky in color, soft and compressible in consistency, and covered by mucous membrane, which, although thin and stretched, still remains smooth and shiny, like the skin of a black grape. . . . (*b*) The *globular or bleeding* pile is single or multiple, and as a rule somewhat pedunculated; the surface of the tumor is roughened and granular, like a strawberry, due to the existence of dilated capillaries. When, however, a portion of it has been repeatedly protruded, the exposed mucous membrane becomes hard, and practically converted into skin, and the columnar epithelium may be replaced by the squamous type. The hemorrhage may be abundant, and comes either from the dilated superficial capillaries, or occasionally from a central arterial twig."—(Rose and Carless' *Surgery.*)

Two methods of cure: "(1) *Operation by the clamp and cautery* is favored by many surgeons. The pile is caught with forceps, and a Smith's clamp, the blades of which, in order to prevent burning, are covered with ivory on the side which rest against the mucous membrane, applied to the base of the pile, in the long axis of the rectum. The pile is then removed with scissors, and the base seared with the cautery at a dull red heat, after which the clamp is removed. (2) *Whitehead's operation* consists in removal of the entire pile bearing area, and is indicated when there are masses of varicose veins which occupy the whole of this region. A circular incision is made at the junction of the skin and mucous membrane; the tube of mucous membrane containing the varicose veins is then dissected up and amputated, and the divided mucous membrane sutured to the skin. Stricture and incontinence occasionally follow this operation."—(Stewart's *Surgery.*)

11. *Hemophilia:* "From a surgical point of view treatment is emphatically negative. It is most important to avoid performing operations on hemophilic subjects, and when hemophilic symptoms are present to abstain from any active measures such as the cautery or aspiration of blood effusions. Prolonged rest and firm pressure are the only methods ordinarily available. Both stitching and cautery are useless, because bleeding occurs from the stitch-holes or from the cauterized surface. The following methods have had some success: (1) *Calcium salts.*—Calcium chloride in 30-60 grain doses or calcium lactate 10 grains hypodermically in a 5 per cent. solution. (2) *Blood serum.*—Fresh antidiphtheric serum is a convenient form. It is given in 20-30 cm. doses subcutaneously or 10-20 intravenously. It has been used as a prophylactic before necessary operations. (3) *Normal blood* applied on a dressing to the wounded surface. (4) *Gelatin,* injected subcutaneously to increase coagulability. (5) *Adrenalin, Ergotinine,* injected locally to contract the bleeding vessels. (6) *Ovarian extract,* given because women are so exempt from hemophilia. (7) *Thyroid extract* may act by supplying a substitute for fibrin ferment."—(Grove's *Synopsis of Surgery.*)

12. *Post-operative ileus* is divided into three classes by Finney: (*a*) mechanical; (*b*) septic; (*c*) dynamic. "While the distinction is very often impossible, the diagnostic features are generally as follows: *Mechanical ileus* is characterized by later onset, visible peristalsis, and severe colicky abdominal pains. The abdominal distention is asymmetrical, and at first there is no change in pulse or temperature. Later the condition is characterized by persistent vomiting and constipation. *Septic ileus* is often masked by the general signs of septicemia, thus differing in its clinical aspect from that of mechanical ileus. A *dynamic ileus* develops as the result of a paralysis of the intestinal muscles, with few of the signs of obstruction and none of the signs of septicemia. The difficulty of differentiating an acute ileus from an acute peritonitis is apparent, and the later the case is seen the more difficult does this differentiation become, for advanced cases of obstruction are almost always complicated by peritonitis. In both conditions the leucocytes are increased, and in both the opsonic content of the blood is very high. In favor of the diagnosis of obstruction are a rapid, feeble pulse; ashy, pinched countenance; rapid distention of the abdomen, which is not board-like; increased peristalsis; early and severe vomiting, soon becoming fecal; severe, cramp-like pain referred to the umbilical region, and absence of fever. In some cases of postoperative obstruction no symptoms appear until weeks or months after the operation. The symptoms are usually due to bands or adhesions. The diagnosis in these cases presents no difficulty. The symptoms of obstruction appear in a patient who has previously been subjected to an abdominal operation. There are other cases in which adhesions following an operation result in incomplete obstruction. In this class, especially frequent after appendiceal operations, the patients present a variety of symptoms. The patient may complain simply of colicky pains, accompanied by more or less abdominal distention and constipation. In other cases there is the history of colicky pains, accompanied by nausea and vomiting, recurring at irregular intervals. A form of postoperative ileus of the mechanical type, to be especially mentioned, is strangulation of a loop of intestine in a postoperative hernial opening. This may occur months or years subsequent to an operation."—(Eisendrath's *Surgical Diagnosis.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

EPIDEMIC ENCEPHALITIS WITH STUPOR.*

BY FOSTER KENNEDY, M.D., F.R.S. (EDIN.),

NEW YORK.

ASSOCIATE PROFESSOR OF NEUROLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE; DIRECTOR, NEUROLOGICAL DEPARTMENT, BELLEVUE HOSPITAL.

IN the past twelve months there have occurred in England, France, and Austria many cases of an acute nervous affection characterized broadly by somnolence, vertigo, ataxia, disturbance of vision, and evidences of interference with the functions of the midbrain and basal ganglia.

The purpose of this report is to draw attention to similar cases now appearing on this continent.

CASE I.—A. B., male, aged forty-two, a patient of Dr. Mefford Runyon of South Orange, whom he first consulted early in January of this year. He complained at that time of intense weakness and inertia approaching somnolence. He had within a couple of weeks become quite disinclined for and unfit for any exertion. These symptoms for the first two weeks of his illness were slowly progressive, but in that period were not sufficiently severe to make him take to his bed; by them, however, he was entirely prevented from doing any work. He attributed his condition to a tapeworm from which he had suffered for over two months. He was seen by his friend and neighbor, Dr. Runyon, on January 17, who was shocked to find him so slow mentally and so much aged in appearance. He complained of inability to read and glasses failed to help him. The left eyelid seemed to lag. His voice was dull and toneless, the face without expression, the head was held looked slightly forward, the arms were held rather stiffly adducted with the elbows flexed, the shoulders were bowed, and the gait festinant. Dr. Runyon was struck by his resemblance to a case of paralysis agitans. The cerebrospinal fluid was normal. The blood picture was that of a secondary anæmia. The Wasserman test was negative in both the blood and cerebrospinal fluid, which was itself normal in other respects. Indicanuria was moderately severe. Appetite was abolished. The systolic blood pressure at this time was 128. He was admitted to Dr. Runyon's hospital, where I saw him in consultation on February 7. He lay on his back in bed, the face mask-like, quite devoid of all emotional expression. The head was rarely moved, and the eyes had the unwinking, staring look so characteristic of Parkinson's disease. This immobility of the eyes, head, and face was present in the rest of the body—all necessary movements were slowly, laboriously, but correctly performed. Mentally the patient was clear, but very inert; questions were answered accurately, but after delay and with every appearance of effort—the voice being toneless and as free from emotional expression as was his face. The ocular movements were ill-sustained and showed paretic jerking on conjugate deviation in all directions. Upward and downward movements of the eyes were limited, but not lost. The pupils reacted sluggishly to light, and still more sluggishly and more slightly on convergence. The optic disks were clear. The tongue movements were normal in amplitude but weak and slow.

Dr. Runyon three weeks earlier had noticed a "lagging" of the left eyelid. This had increased by the time of my examination so that the left lid in rest was partly dropped and at the same time could not be completely closed. In short, innervation to the left eyelid was defective in both the third and seventh cranial nerves. There was a well-marked weakness of the left facial muscles of peripheral type—a typical incomplete Bell's palsy. He could swallow without accident, but did this act as all others, slowly and with an appearance of toil.

The entire musculature showed great increase in tonus, similar in kind but greater in degree than that found in most cases of shaking palsy. His weakness was largely subjective; power was good. Rigidity was more marked on the left than the right side. There were no signs indicative of changes in the motor tracts; the deep reflexes were present but not easy to obtain.

FIG. 1.—Case II, showing myasthenic facies and catatonic attitude.

There was generalized profuse sweating, the complexion was muddy and the tongue quite dry and heavily furred.

CASE II.—J. D., male, aged thirty-two. Seen at Bellevue Hospital. In the middle of January he struck his head on rising quickly from a stooping position in a bank vault. He had no immediate symptoms, but complained of severe headache during the next few days; he became sleepy and would not play as usual with his children. He had a temperature of 102° F.; his condition was diagnosed as influenza. During this first week he had spontaneous nose bleeds on three days—this is not an unusual circumstance with this man. After seven days' illness he was continually drowsy, and is said to have been rambling in his speech and to have been unable to recognize his wife. From the date of admission to hospital, January 26, to the present time—a period of about six weeks—his condition has been variable as regards the depth of his stupor, but at all times it has been possible to rouse him by sharply spoken orders or by shaking his shoulder. He has always

*Read before the Practitioners' Society of New York, Friday, March 14, 1919.

been clear in his mind under our observation, commands have been slowly but properly executed, and all questions tediously but clearly answered; on the other hand, he has expressed no emotion whatever, either in facial expression, by gesture, or in his speech. There is severe but incomplete ptosis of both eyelids; the eyes cannot be closed firmly. The pupils are unequal and react very sluggishly to light and not at all on attempted convergence. Conjugate movements of the eyes upward is defective and unequal, and neither eye can be swung downward below the horizontal. Paretic jerkings of the eyeballs occur on looking to either side, which movements further are not complete.

The mouth is habitually held agape—its corners lag and the normal creases which lend expression to the face are smoothed out. This man does not remind me of Parkinson's disease in his appearance; he has a facies differing in no respect from those of persons suffering from advanced myasthenia gravis.

From the beginning of his illness he has had definite weakness in the right facial muscles; but this is only an aggravation of the paresis manifest in all. The head is held stiffly, but on command he can put his chin on his chest. Kernig's sign is absent. The abdominal reflexes are normal; the deep reflexes depressed and the plantar reflexes have been indefinite in type. The arms are held stiffly, as are the legs. Usually he maintains any position, however fantastic, in which his arms

Fig. 2.—Case III, showing characteristic attitude of the hands; the patient improved rapidly and when photographed had largely lost his mask-like expression.

are placed, but this catatonia differs from that seen in some psychoses in the ability of the patient to correct his attitude on command. Without this stimulus, however, he lacks the initiative to move his limbs from any position, however uncomfortable or grotesque. The tone of the muscles seems lowered; they themselves are flabby to touch, but the tendons and ligaments are tense, so that there is produced a state approximating the waxy flexibility of dementia præcox. This increase in ligamentous tone gives an air of spasticity to the limbs.

When first seen there was a coarse tremor in both arms, and such movements as are involved in the finger-nose test were accompanied with much motor ataxia. These symptoms have now passed and the arms are held in the rigid attitude described in the first case.

The blood pressure is $\frac{112}{78}$. The man looks profoundly toxic, the tongue dry, swollen, and furred. Percussion of the pectoral muscle produces at the site a slowly transient tumefaction with a visible vermiform contraction propagated in both directions along the muscle fiber—phenomena not characteristic, of course, of this disease, but seen in many conditions accompanied by marasmus and toxemia. The urine is normal, as is the cerebrospinal fluid. On January 30 the leucocyte count was 11,400, of which 53 per cent. were polynuclears. Rather less than a month later these figures had changed to 26,500 and 90 per cent. respectively.

Case III.—W. F., male, aged fifty, a chauffeur. Admitted to Bellevue Hospital February 16, complaining of drowsiness and general weakness. His illness had begun three weeks earlier with headache, dizziness, and inability to keep awake. This latter was so pronounced as to make him fall asleep, not only in his chair during the day but, latterly, also at his work. At the same time he became very weak and incapable of exertion.

On examination, he was found to have the mask-like facies so evident in the patient first described. Profound emotional stupor, but the mind behaved lucidly under stimulation. The eyes were held fixed in an unwinking reptilian stare. The head never moved. The arms and hands were ordinarily held in the attitude characteristic of paralysis agitans and showed a coarse tremor, more evident at rest than in action. This tremor was also present in the lower limbs. Rigidity was everywhere manifest. Catatonia was extreme. There was profuse general sweating—a condition most evident in all my cases. Incontinence of urine and fæces often occurred, the result in some measure of his inability to initiate enough activity to secure attention.

The pupils were ectopic and reacted sluggishly to light. Accommodation was badly carried out. Conjugate deviation of the eyes upward was much limited and all downward movement was lost.

The optic fundi in all these cases were clear. The abdominal reflexes were present; the deep reflexes were present, but reduced apparently by the failure to secure tendon relaxation; the plantar reflexes usually were on the right side of flexor and on the left of extensor type.

No abnormality was found in the urine or cerebrospinal fluid. There was a leucocyte count of 10,000, of which 77 per cent. were polynuclear cells. Blood culture was negative, except for a white staphyloccal contamination.

Case IV.—Male, aged forty-seven, physician. Seen in Hartford, Conn., three days ago (March 11), a patient of Dr. Kingsbury.

Four weeks earlier he had developed severe intermittent headache, associated with vertigo sufficiently severe to cause him to stagger in walking. Transient diplopia occurred within a few days. The temperature was then 102° F. and has reached this height irregularly since. Intense weakness and drowsiness was an early symptom and has varied in intensity. Always clear mentally, but quite lacking in initiative. The cerebrospinal fluid has twice been found normal. Urine normal.

Profuse sweating. Toxic tongue. Myasthenic facies. Weakness, especially in right face, but without much facial power of any kind. Rigidity of posture. Catatonia. Absence of power of convergence of the eyes. Pupil reaction for accommodation lost and sluggish to light. Absent upward and downward movement of the eyes. Deep reflexes depressed. Abdominal reflexes brisk on the left side and absent on the right. Plantar reflexes indefinite. In the past week, while emotional stupor has been lighter, there has been a progressive increase in pulse rate and complete gastrointestinal atony. For ten days there has been retention of urine and an inability to expel even enemata.

These cases have been discussed in some detail in order to depict the development and character of the clinical pictures. In the past week seven other more or less similar cases have come under my observation. In all, the diagnosis has been manifest. Stupor, however, varied in degree and was absent in one, a girl of sixteen, in the Neurological Institute; in her case there was the usual history of onset with headache, vertigo, and diplopia over about a week's time, together with at present Third and Seventh nerve palsies, much increase in tendon tone and pronounced coarse tremor of the right extremities. Another case, a man aged thirty-five, seen in Bellevue Hospital, has no emotional stupor, but lies curled up in bed complaining of headache, fretful, and irritable. He vomits from time to

time and presents inability to look above or below the horizontal and lacks the power of visual accommodation.

It would seem certain, then, that we now have to do with the same disease as was described by Economo in April, 1917, in Austria; by Netter a year later in France, and at the same time by various British observers in England.

The clinical picture described by these workers is so clearly cut as to be easily recognized, and there is no difficulty in establishing the identity of the symptom complex in these American cases with that seen in Europe, especially in the past twelve months. The picture in the main is that of an acute illness ushered in by a moderate pyrexia and usually associated with headache, vertigo, diplopia, and progressive emotional stupor; ingravescent palsies of the cranial nerves, especially those of the midbrain and affecting ocular movements; catatonia with increase in tendon tone, tremor in the limbs, and variable evidences of damage done to the long motor tracts.

Brains of those in whom the disease has proven fatal show minute hemorrhagic areas, usually discrete, rarely confluent, grouped in the subthalamic area, throughout the mesencephalen and the aqueduct. Microscopically, a perivascular parenchymatous infiltration is seen consisting of plasma cells, lymphocytes, and many giant glia cells. Marinesco most guardedly reports finding diplostreptococci in some of his specimens, and Economo makes a similar claim, not with regard to his human material, but in the brain of a monkey infected subdurally by an emulsion of spinal cord and brain from a fatal case.

The symptomatology proceeds logically enough from the character and site of the lesion—the interruption of afferent impressions to the thalamus producing sleep; the affection of the cranial nuclei, the local palsies; the interference with the long tracts, the tremors, and reflex changes. One may remember the affective palsy of one side of the face in cases of compression of the opposite optic thalamus when observing the failure of these patients to express themselves emotionally, and again the peculiar rigidity and spasticity following lenticular nuclear degeneration, and realize that the incidence of this disease should make for increased knowledge concerning the functions of the basal ganglia.

So far there has been no family grouping suggesting contact infection. Macnaulty in his report quotes the proven existence of diplococci of Weichelsbaum in the nares of persons not suffering from cerebrospinal fever, as an explanation, by individually lowered resistance, of the sporadic incidence of this disease, as also of poliomyelitis.

I am not impressed personally by the arguments which try to show that acute poliomyelitis and epidemic stupor are one and the same condition—further, it is not evident that this disease is a sequela of influenza in each individual, though similar symptoms have been described as having appeared during and after previous influenzal epidemics.

The mortality does not exceed twenty-five per cent, and in most series is much lower than this.

In fine: The etiology is conjectural, the diagnosis is uncomplicated, the contagiousness unproven, and the therapy symptomatic.

20 West Fiftieth Street.

THE PSYCHOLOGY OF SUCCESS IN MEDICINE.*

By ANTHONY BASSLER, M.D.,

NEW YORK.

PROFESSOR OF GASTROENTEROLOGY, FORDHAM UNIVERSITY MEDICAL COLLEGE AND NEW YORK POLYCLINIC MEDICAL SCHOOL; CONSULTING GASTROENTOROLOGIST, PEOPLES, CHRISTS, POLYCLINIC, BETH-DAVID HOSPITALS, ETC.

ALTHOUGH a debutante as one of the teachers in this school, through the kindness of our president, I am privileged to address you on the happy consummation of your ambitions as medical students—namely, the conferring of the degree of M. D. On several occasions in my life I have sat as you do, listening to an address which at the time seemed wise and useful, but was quickly forgotten and not recalled or understood until years afterward. I do not expect any better luck for such remarks as I make tonight, because the psychology of things with you now is one of joy, a reaction from the years of study you have gone through. It took me several years to appreciate the significance of a remark made by the late Dr. Joseph D. Bryant at my graduation in medicine, a remark that gathered in significance as I went on. Substantially he said: "Do not think you have reached the top of your climb and sit down with your diploma. You have just begun, and now, as well as at all times in your future, he who sits down in satisfaction will soon observe that he is facing down hill." With the much improved and more complex conditions about practice today than twenty-one years ago, when I graduated, this will be even truer for you than it has been for me.

Being physicians, many will be the pitfalls that shall surround you. As historian of my class, one of about 150, I recall that only five are teachers of note today. Perhaps about 25 are prominent practitioners in their communities; the largest proportion are working in ordinary practices; not a few have fallen by the wayside from unfortunate habits; sad alliances bringing on harrowing climaxes in others; the almshouse and other asylums have gotten some, and about a third died in the early forties. This, surprising as it may seem, is not a bad record as college statistics go, and it is the record of what was considered at the time the best class the school had graduated in many years. With your permission, then, I will endeavor to draw one or two conclusions, presenting these on the basis of the psychology of daily life in the practice of medicine, with the hope that something I may say will be of service to you toward arriving at success in your future years.

Live as exemplary a life as possible. Remember that in our work we are servants of the people, and the people often expect more of us in living moral and normal existences than they do of themselves. Always remember that a physician is a semi-public man, held up and looked up to when the public respect him, and over-criticised when it does not. Nothing destroys a physician's reputation quicker than that he is too familiar with both men and women, that he is loose in his habits; fond of cards, horse races, drinking, etc., not capable of being gotten at when needed, and too confidential about his personal affairs with his

*Address delivered to the graduating class of the Fordham University Medical College, February 19, 1919.

patients so that they know and batter to and fro his domestic troubles. If your character is like the spire of the flame, ever heavenward however the candle is inclined or bent, and your personal desires and domestic life always toward the best, then the untruths said about you can only enhance and outline your character.

Success in medicine, like everything else in life, is always relative. Such as there is is resident in achievement, in which satisfactions abound. Against accompiishing, however, the inherent tendencies of the human mind militates, and against these dangers we must be constantly on our guard. The method of doing things is commonly the first one that promises results. Largely it is unconsciously adopted and this unreflective adaptation is not always the best, because it is usually the one which requires the least expenditure of energy and thought. Learn the habit of attending to details, and in overcoming obstacles, keep as far away from the "trial and error" method as possible. Man is gifted with intelligence, but many do not reason as they should. Unreflective—unconscious —adaptation was the method of progress in the early history of medicine. It rested upon authority and the trying of one thing after another. Massaria, of Padua, in the sixteenth century, would rather be wrong with Galen than right with any other physician. Naturally no great progress was made.

But today scientists no longer wait for the tedious, unintelligent elimination of mistakes. They set definite problems, study the conditions, and then plan their investigations so that the errors of earlier workers may be eliminated. But the scientific plan has not been as generally adopted in medicine as it should be. We still wait for something to turn up and then adapt ourselves as best we can. You see I am arguing for research and study, and nothing in medicine is so small that it should not have these at all times. There are so many shades and nuances that unless we have this policy as cardinal, experience will not be a filing-case of facts which we can interpret with proper attitude. One of the pitfalls of progress is not so much lack of experience as it is in proper make-up of the experiencer. The new physician must have a method of progress, must make it his business to criticise experience and not accept things on appearance alone, or take them for granted.

The general practice of medicine, which I hope you will all go through for a period of time at least, becomes rather uneventful and tends to mental stagnation, and after a time retrogression. Always keep up your interest, perseverance, and determination. Therefore keep in contact with hospitals, clinics, medical societies, and the teachers. Go where you will have and feel opposition. This does not put brains in men but draws the best out of them, and however strong the obstacles or adverse the circumstances the better you should become. Physicians as a rule move along lines of least resistance, and this tends to lower the maximum efficiency and reduces the dimensions of the job and themselves. This is racial indolence, because with the proper spirit and enough of it, no job in medicine cannot be made a big one. Remember that while the general death rate has declined in recent years, because of the improved conditions in handling infants, children, and young adults during the last thirty years, the death rate from organic diseases has increased 94 per cent. in fifteen American cities. There are many reasons for this increase in heart, liver, kidney, and blood-vessel conditions, but there are many more, in fact the most important, that are still to be found out. You are coming into the profession at a wonderful era in medicine. Will to do your share in it by keeping in mind that scientific medicine is your duty, and will to do it with a type of mind that accomplishes in substantial ways, even though the environment in which you do it is humble and remote.

If you adopt the policy of careful scrutiny and maintain a plan of effort, thinking will not be a spontaneous process, like breathing. One gains little from the mere succession of experiences or things thought of. Experiences, things, and ideas must be related and correlated. The success or failure in achieving depends upon the accuracy of the process of thought, and this depends upon fundamental principles. In addition to what you deduct from your own experiences, try to discover meaning in the experience of others, and reconstruct it in terms of personal experience. Never be a literal man with no sense of proportion and no sense of humor. Such men never can interpret experience, and only follow rules and prescribed modes of action. With understanding, emergencies and deviations are best met, and as physicians we deal with these all the time. Experience is always prospective. It looks toward the future and furnishes fundamental principles. These principles are rules of action and the mediocre mind follows them to only mechanical efficiency. But when the primary training of the mind is penetrating and the interpretations good, then comes a flood of suggestions and you see deeper meanings than the rules express. There is a vision in some physicians, a sagacity which is amazing to the moderate mind. This wisdom is not genius, nor a miraculous product. It comes through early association of ideas, organization of knowledge and experience. A physician cannot become great on nothing, and no amount of information can make him wise. It comes because he has worked hard and also worked hard with himself, things I hope you will also try to accomplish, so that when responsibility falls upon your shoulders your Alma Mater and the teachers here will have joy in your achievements.

There is an old proverb, "Beware of the young doctor and the old barber." This was true when written, but today the world knows that the young physician is the best trained and fears him not. It's now only true of the barber. So your youth is really an asset for making your living in medicine, although don't expect the older physician to acknowledge or respect it. Your teachers get along with that nicely by being tolerant and having hopes for you. I was once young like you, and today I know this must be true in the way they put up with me as I was. What is surprising too is that your teachers never seem to forget you, remembering your faults as well as your virtues. One of my old teachers said to me only a few years ago that as a young physician I had given him some very trying moments, but that his hopes

for me, thank God, had been realized. Of course you do not think yourselves anything like I was, although when you marry, and you must all do that some day, you may, in a son who has just graduated in medicine and with whom you argue a case, a condition, or the treatment therefor, see the replica of yourself in how you were at graduation.

And now as you scatter from this University, I hope that you will always appreciate what the Professors and the good Fathers here have done in their efforts for you. Theirs has been a labor of love for the art of medicine, and interest in your behalf. We all hope your lives, careers, and successes will give us happiness, that ultimate joy that comes when one labors for a cause or for the devotee in it. Ours is a noble field of work, and you ennoble yourself by being graduates in it. Permit me to congratulate you most heartily.

THE EARLY TREATMENT OF FACIAL PARALYSIS.

By WILLIAM MARTIN, M.D.,

ATLANTIC CITY, N. J.

Recently the writer read an interesting paper* upon the etiological factors bearing upon the therapy of Bell's palsy, and in the course of the paper there appeared the following paragraph: "During the first ten days to two weeks no electricity should be given whatsoever. But about the end of this time a test should be made electrically to determine the amount of damage done. If faradic irritability is present in any degree, a more favorable prognosis in store for the patient. I have seen these patients get better within two weeks." The author then goes on to those cases of longer standing in which may be found the reaction of degeneration with their less favorable prognosis, and he then further outlines their treatment electrically, using the well-known interrupted galvanic current.

There are some points in this paper that will bear investigation as to their merit. Why should we delay even ten days before treating electrically? These statements are not followed by an explanation so that one can properly judge their correctness, so they are open to question.

As neuritis may be recognized as the factor involved in a fair number of cases, there can be nothing gained by waiting for the neuritic process to extend. The logical thing to do would be to get at it at once when recognized, and the only method of treatment of avail is the electrical. This does not mean the use of the interrupted galvanic current, but the more modern method. As in any case of neuritis, we have the inflammatory exudate causing mechanical pressure at the points of exit of the nerve and naturally this must be removed before a cure can be had. The best current for this effect is the static wave current, which by its mechanical action, causes frequent contractions of the tissues, thus breaking up adhesions and clearing out the exudate.

It can be readily seen that the longer the exudate remains in situ the more likely is it to become organized, and thus make additional pressure with the resultant effect of interrupted motor and sensory function.

Hyperemia appears to be one of nature's methods of restoration, and in her effort to secure this, we often have a circulatory stasis instead. If, therefore, we can produce a true hyperemia, it would seem logical to believe that we could restore function, granting that the pressure had been removed from around the nerve. This calls for radiant light and heat, produced by radiations from a high-candle powered carbon-filament lamp properly hooded, so that the rays are thrown in parallel. This applied over the face to a point of active hyperemia, will meet the requirements. The two treatments mentioned, static wave current and radiant light and heat, should be used as early in the case as possible after the paralysis happens, for the rapidity of relief and cure depends upon this early treatment.

In those cases that the physician unfortunately does not see as early, there must be used in addition the slow surging sinusoidal current, the basis of which may be the constant or galvanic current, if preferred. The interrupted galvanic is a harsh method of applying the current, and once a patient has the sinusoidal used, it will be impossible to have his consent for the use of the interrupted current, for the difference is so marked when comfort is considered, that they cannot be placed in the same class.

As an etiological factor we must not lose sight of focal infections. As these cause a neuritis of other nerves, so may they be the cause of facial paralysis, and all tooth abscesses, pyorrhœal pockets, and other foci, must be eliminated before we can expect to secure the effect that we desire.

In the writer's experience there have been cases of atrophy of the facial muscles in cases of facial paralysis of only two months' standing. This shows the danger of delay. In every case of this kind, it has occurred as the result of the physician's advice to wait before doing anything. Such advice usually calls for six weeks delay before using electricity, and is the result of medical teaching of decades ago, from which many do not seem to have recovered, in spite of what has been since taught by modern electrotherapists.

Within recent time three cases came to the writer's notice that illustrate what this paper is meant to imply, the danger of delay. These cases came within two days, one being a case a week old, another six weeks old, and the third of over two months' duration. The latter had well advanced atrophy and all the physical signs exaggerated. It will not be necessary to go into detail concerning the treatment of these, except to say that it was instituted at once in all cases. The first promptly got well under electrical treatment, being of less than two weeks' duration; the second improved considerably in three weeks, but did not continue treatments until entirely cured, while the third was forced to continue them for nearly two months.

In the latter case the atrophy entirely disappeared, but there remained for a considerable time

*J. H. Lerner, M.D., "Study of Etiological Factors Bearing on the Therapy of Bell's Palsy, Based on a Review of 177 Cases." Medical Record, February 22, 1919, pp. 319.

the inability to pucker the mouth sufficiently to whistle. This finally came also, and the patient was discharged cured, but somewhat sore about the physician's advice of delay in treatment.

In the writer's judgment, this cannot be too much emphasized, that in delay we have danger, that all cases must receive prompt treatment, and that if modern electrical methods are used, we will have prompt results from prompt treatment.

RABELAIS' MENTION OF THE MUSCLES.

By Douglass W. Montgomery, M.D.,

San Francisco, Cal.

The physiology of the Middle Ages rested on the sentiments and feelings and for this reason alone is well worth studying, as sentiments and feelings now, as always, are the predominant and fateful features of human character. The sciences on which physiology and the practice of medicine now rest were unknown, and yet physicians were successful, had large and lucrative practises and great influence, as, for example, Rabelais himself.

What might be called the spiritual point of view in ancient physiology is nowhere better exemplified than in the conception of the action of the muscles.

The energy moving a muscle was not supposed to arise in the muscle itself, but was assumed to be transmitted to it in the form of spirits from the brain. Roughly speaking, the food was endowed; in the liver with natural spirits; in the heart with vital spirits; and in the rete mirabile and in the cerebral ventricles with animal spirits. The epithet animal has here not the same signification as with us, but referred to the soul (Latin, *anima*, soul). These animal spirits were assumed to be a most subtile fluid, and were transmitted from the brain to the muscles through the nerves, which were thought to be hollow. The idea that the nerves were hollow persisted long after the introduction of the microscope, as a medulary nerve, examined fresh shows a central core which appears to broaden out, and becomes obscure on raising the objective, and on each side of this core a border, which grows brilliant as the objective is raised.[1] In France, even yet, the nerves are called "*tubes nerveux*."

By means of these animal spirits the brain gave both sensation to the nerves and motion to the muscles.[2] The brain therefore was regarded as a force-producing, not merely a governing and regulating, organ.

Following out this idea of cerebral spiritual energy, Rabelais considered the animal spirits powerful, and compared them, in his fantastic figure of Lent, to mighty blows with the fist.[3] And in regard to the mode of transmission of these spirits he said the nerves, which were also supposed to be provided with valves, were like a faucet.[4] Furthermore, in the same fantastic figure, Rabelais compares a muscle to a bellows. Le Double has shown that the old spindle-shaped French bellows resembled the spindle shape of a conventional muscle, and its swelling and relaxation in action also carry out the same idea, so that in such a conception the animal spirits could also be naturally compared to the air inflating a bellows.

In those days the tendons and aponeuroses represented the strong part of the muscular system, and what we now call muscle was considered packing. This view had real common sense in its favor. Muscles were known to be strong, and the strong tendons, and the strong connective tissue fibers spreading out from these, were obviously stronger than the soft friable tissue making up the mass of what is now known to consist of muscle fibers. It was not till long after Rabelais that a Dane named Niels Stensen[5] and an Italian named Borelli[6] recognized that what we now call muscle was the real contractile part of the organ, and that what we now call the tendon and its fibers were the passive transmitters of muscular energy.

The Will and Voluntary Muscular Effort.—The muscles are the motor organs of the body, and many of them, those called voluntary, are admirably subservient to the will.

As soon as it became accepted, as it was in Rabelais' day, that the will resided in the brain, then the feeling of making an effort naturally also would be referred to the brain.

Take as an illustration the case of an ocular surgeon afflicted with the palsy and tremulousness of elderly life, who, when operating for cataract becomes absolutely steady. Here the old discipline and habit come in to aid the power of the will to control temporarily the failing steadiness. When the effort of the will is relaxed the palsy returns. It would be perfectly natural for such a man, under such circumstances, to refer the real seat of power, as well as the government of it, to the brain.

When the energetic and able monk, Friar John, was turning a band of the marauding army of King Pichrocole out of the vineyard of the Abby of Seuillé, if any rascal of them showed an inclination to resist him, the determined priest immediately gave him a sample of the strength of his muscles, and transpierced his chest by way of the mediastinum and the heart.[7] This indicates clearly that Rabelais considered the muscles as the motor organs of the arms. But in a physiological system built up on sympathetic and temperamental lines, the entire conduct of the monk, impelled as a harmonious whole by his fighting and imperious will, would lend itself to the idea that the power itself came from the brain.

Again, when Gymnaste, the esquire of Gargantua, was doing all sorts of circus tricks before the astonished men of Captain Tripet's company, he, in one of these tricks, sustained his entire weight on the muscle and nerve of the thumb placed on the bow of his saddle.[8]

In those days tendons were also called nerves, and undoubtedly the author refers to the magnificent tendon of the flexor *pollicis longus*. The whole scene refers to the action of the will carrying the body through all sorts of graceful motions, and is therefore an example of the old sympathetic view of physiology, conceived before oxygen or carbohydrate were ever dreamed of.

The word nerve originally meant the string of a bow, and bow strings were frequently made of sinews, so that it was natural to call any string-like structure in the body a nerve. Our old proverb, "Money is the sinews of war," occurs in Rabelais as "*Les nerfz des batailles sont les pe-*

cunes," and in this he only follows his Latin predecessors, as, for instance, Tacitus, "*Pecuniæ belli civilis nervi sunt.*"[9] It is interesting to note that in this proverb the idea of strength is referred, not to the true muscular substance, but to the tendons.

In the following situation in Rabelais, however, the term "nerve" is employed in the sense in which we now usually use it:

Out of love of mischief, Friar John, while on ship-board before the Island of Ganabin, induced Pantagruel to order a salute fired to the Muses, and, as he alleged, to prevent the powder going bad in the cannon. The real reason was to frighten Panurge, who was below decks, and therefore got the full effect of the noise of the explosions. The manœuvre was a complete success. As Rabelais puts it, the restraining virtue of the nerve which restricted the sphincter muscle (*sphincter ani*) of Panurge was relaxed.[10] This muscle is circular and has no tendon, so that the word nerve cannot here mean tendon, and must therefore refer to the nerve. It shows clearly also that Rabelais understood that the nerve had an influence on muscle, which, like the production of motion by muscle, was a very old observation.

There is still another reference to muscle of which I do not know the meaning: In the great public altercation by means of signs between Panurge and the learned Englishman Thaumast, the latter made a sign by striking the middle finger against the muscle of the palm, which is below the thumb (*le muscle de la vole qui est au dessoubs du pouce*).[11] By "muscle of the *vola manus* lying below the thumb," Rabelais undoubtedly meant the whole thenar muscle mass, which had not, in his day, been dissociated into its separate elements of the short abductor of the thumb, the opponens, the short flexor, and the adductor.

This sign made by striking the middle finger against the thenar eminence may have had some special meaning in the Middle Ages, now altogether lost. It was an age, as we know, particularly rich in signs and salutations, and appertaining ceremonies and precedures, many of which still linger in medieval governments, and which no doubt will give rise to many a shock to sensitive nerves in the diplomatic relationships between America and her European contemporaries after the present war.

EXPERIENCES WITH NEODIARSENOL (CANADIAN NEOARSPHENAMINE); 241 INJECTIONS WITHOUT ILL EFFECTS.

By HERMAN GOODMAN, M.D.,
FIRST LIEUTENANT, M. C., U. S. A.
VENEREAL OFFICER, CAMP LAS CASAS, PORTO RICO.

RECENT articles based on few observations, and without fully citing the method of administration have created a wrong impression concerning the neodiarsenol brand of neoarsphenamine which an experience with the drug in 241 injections to 100 women has failed to sustain, and which is thought to be of sufficient interest to warrant publication.

Neodiarsenol is made in Canada. The drug comes in ampoules and is canary yellow in color. It is powdered and does not cake in the ampoules. A small file, glass rod, and a sheet of instructions are in the container (sealed cardboard box), which latter carries the control number. This number is different for every tube, and the number is not carried on the label of the ampoule. We received one lot shipment of 500 ampoules of 0.9 grams with the control numbers about AZ6300.

In the preparation of the drug for intravenous use, rigid asepsis was observed. The apparatus was boiled just before using in distilled water. The water for the solutions was always freshly distilled (never more than six hours old), boiled, and cooled to room temperature. Solutions were prepared for six patients at once and since we were working at the Hospital Jail at Ponce, and were using two tables, each with its trained operator and assistants, all the solution was used within fifteen minutes of its preparation. One doctor made all the solutions.

One hundred c.c. of cooled freshly distilled water was put into an Erlenmeyer flask of 250 c.c. The neodiarsenol ampoules were opened by scratching the neck with a file, and gently tapping the end. The heated glass rod was not used. The powder was dropped on the water. Water was then added to make up the necessary bulk which was 30 c.c. for each patient. The flask was then gently rotated and the powder went into solution readily. It does not dissolve with the ease of the neosalvarsan of the Germans. Small particles persist for at least half a minute longer than the main bulk of the powder, but it has not been necessary to filter. We use the gravity method for the injection with the Fordyce needle. The solution is injected at room temperature.

The patients are always prepared for the injection by having the bowels emptied by a cathartic taken the day before, and by omitting the previous meal. Following the injection, the patient lies down. Only fluids are permitted (milk, coffee, or soup, and plenty of water), for the rest of the day.

Injections were given at weekly intervals to 100 women in the latent tertiary stage of syphilis, all of whom had four plus positive Wassermann reactions. In 52 cases, a full course of three injections was given. In the other cases the women had been released. Thirty-seven women

received the first two doses and 11 women only one. The initial dose was 60 centigrams; the second 25, and the third 90. The amount of fluid was 30 c.c. for each injection.

Although on the lookout for reactions, and the patients volunteered complaints readily enough when complaints were due, we had only 12 reactions of the delayed mild evanescent type. Headache was a symptom in seven cases, but it never lasted longer than 12 hours. General flushing of the skin accompanied this headache in 4 cases. Pain in the abdomen was complained of 4 times. One woman vomited about five minutes after an injection of 0.9 gm.

Further experience with neodiarsenol, in which three doses were administered within three days, is being reserved for another paper.

Summary.—Neodiarsenol was injected 241 times in 100 cases. With proper care in the preparation of the glassware, freshly distilled water that has been boiled and cooled to room temperature, and the patient prepared, the injections of neodiarsenol were not attended proportionately with any greater number or kind of reactions than the injections of 147 doses of arsenobenzol (Schamberg) which we administered to 59 women during the same period.

A NEW INCISION FOR APPENDECTOMY.

By LEIGH F. WATSON, M.D.,
CHICAGO.

MANY writers have noted that in the cadaver the base of the appendix is found at McBurney's point, while in the living subject it is below this point, usually on a level with the center of Poupart's ligament. A number of operators have called attention to the ease with which the appendix can be removed when operating for right inguinal hernia. Since 1910 I have used a new incision with its center over the base of the appendix, and believe that in many cases it is an improvement over those in general use.

Incision: A point one and one-half inches from the right anterior superior spine, on a level with a line connecting the two superior spines, is selected for the beginning of a vertical incision which extends directly downward for two to three inches to a point just above and to the inner side of the internal abdominal ring.

Advantages: Traction to expose the appendix is avoided, because this incision, in the external oblique and its aponeurosis—the most resistant structures, is directly over the base of the appendix. It can be enlarged without weakening the abdominal wall. The ilio-hypogastric and ilio-inguinal nerves are not injured because the incision lies between them. Because this incision is made over the cecum, the small intestines do not crowd into the wound as they do with the McBurney and lateral rectus incisions.

Medicolegal Notes.

Liability of Hospitals for Employees' Negligence.—In an action against a corporation owning a hospital for the negligence of a nurse, the California Supreme Court holds that the question of whether a hospital is a charitable institution or is operated for profit is determined, not alone by the powers of the corporation as defined in the charter, but also by the manner of conducting the hospital. The purposes outlined in the articles of incorporation of the defendant corporation were almst as broad as the field of Christian philanthropy, extending its limits throughout the whole world. They included power to devote the funds of hospitals founded by the corporation to engage in the promulgation of hygiene, temperance reform, and Christian philanthropy and to manufacture and sell hygienic goods and sanitary products. The sanitarium founded had been operated at the time of the injury to the plaintiff for 13 years (1898-1911) without having at any time received any charity patients. Whatever the intent of the organization generally, the court said, it was evident that the hospital itself was being used as a money-making institution and should be treated as such, unless the fact that the corporation was a non-profit making corporation and that all money made in the hospital was ultimately devoted to some charitable purpose would prevent that. The trial court found that the hospital was in fact operated for profit. On appeal it was held that the evidence supported this finding, and the court saw no good reason for exempting the defendant from the liability incurred by other hospitals conducted for profit.

Although it was unnecessary for the decision of the case to pass upon the nonliability of public charitable hospitals for negligence or the reasons therefor, the court referred to the fact that the courts of this country have almost unanimously arrived at the conclusion that hospitals organized for charitable purposes are not liable to their patients for injuries arising from the negligence of their employees, where reasonable care is used in the selection and retention of them, although the reasons given for this rule vary in the different states. The most liberal theory of exemption is that based on what is known as the "trust fund theory," that is, on the proposition that the court will not allow funds held in trust for a charitable purpose to be diminished by the payment therefrom of damages due to the negligence of those employed by the trustees in charge of the trust property. The court cited the recent case of Gamble v. Vanderbilt University (Tenn., Feb. 9, 1918), 200 S. W. 510, to the effect that a corporation organized to conduct a public charity may also conduct an enterprise for gain and be liable for the negligence of its employees in such enterprise, although the profits derived therefrom are devoted to the general purposes of the charity. In reference to the trust fund theory of nonliability the court in that case said "How this shall be applied to particular cases or classes of cases is a matter in the wise discretion of the court of each jurisdiction, according to their conception of sound policy. . . . Public policy is not a thing inflexible. No court is wise enough to forecast its influence in all possible contingencies. Distinctions must be made from time to time as sound reason and a true sense of justice may dictate."—Stewart v. California Medical University and Benevolent Assn., California Supreme Court, 176 Pac. 46.

Construction of Harrison Anti-Narcotic Act.—In proceedings for violation of section 2 of the Harrison Anti-Narcotic Act it was unsuccessfully contended that to dispense or distribute the drugs is not to sell, barter, exchange, or give them away. The Federal District Court for the Western District of Pennsylvania held that it could hardly be said that words of so broad import as "sell, barter, exchange, or give away," when standing together, were intended by Congress to be so narrowly and strictly construed as to include only those cases where title to the prescribed drug was in him who undertook to dispense or distribute it. The lawmakers were not concerned with the ownership of the drug, but with its unlawful distribution. The statute was held to be constitutional.—United States v. Jin Fuey Mong, 253 Fed. 213.

Medical and Surgical Lessons of the War.

SANITATION IN WAR.

By Col. GEORGE G. NASMITH, C.M.G., Ph.D., D.Sc., D.P.H.,

TORONTO, CANADA.

SANITARY ADVISER AND OFFICER IN CHARGE WATER SUPPLY, FIRST CANADIAN CONTINGENT; OFFICER COMMANDING CANADIAN MOBILE LABORATORY, B. E. F. FRANCE.

It should be remembered in dealing with this subject at the present time that none of the warring countries of Europe have so far published statistics as to morbidity and mortality from preventable diseases. Though numerous papers have been published on special researches and phases of medical or sanitary work, little of a general character has been written. There is no summary available, for example, of the general sanitary methods and procedure followed in any given war theater, and naturally so, for during war one does not publish anything that may be of value to the enemy.

We are therefore at this date compelled to speak in general terms of sanitation in war, and, naturally to view the problems from the angle most familiar to us. In the case of the writer, experience of sanitation in war was gained during some two and a half years with the original Canadian expeditionary force in England and the British army on the Western front. Consequently sanitation as practised in the British army in France will be the practical basis of this article. The British medical and sanitary officer has had opportunities unrivalled by any other country in the world. Having to control the health of communities as great as India with her 300 millions of people and as varied as those of Egypt, Central and South Africa, Australia, Canada, West Indies, British Guiana, and Hong Kong, she has had to meet and endeavor to solve every sanitary problem known to humanity and has in consequence an unrivalled wealth of experience to draw from.

Naturally therefore it was to be expected that sanitation as carried out in the British army would be inferior to none, and that freedom from epidemic disease and a low morbidity and mortality rate would be found. Such proved to be the case. It may be said in general that in the first year of the war the British sanitarian had encountered and solved all the sanitary problems that were capable of a practical solution and had established a system that subsequently needed but little alteration. No apology therefore is necessary for taking the British army as a model from the standpoint of sanitation and hygiene.

The maintenance of the health of soldiers and the prevention of communicable disease is, in theory and practice, a comparatively simple matter provided you have proper medical organization and discipline of troops. This is particularly the case in permanent camps, where conditions are fixed, apparatus is stationary, extra assistance from civilian sources is always available, and soldiers are under absolute control. It is a simple matter in permanent camps to evolve a set of cast iron rules to be followed and to install the necessary sanitary apparatus. It becomes increasingly difficult to keep an army in a sanitary condition as front line conditions are approached.

In the temperate climate of western Europe the vast majority of communicable diseases of importance from the military standpoint are contracted largely in three different ways which may be outlined as follows:

Group 1. From intestinal excretions; *e.g.* cholera, typhoid fever, dysentery, etc.

Group 2. From throat and nose secretions; *e.g.* diphtheria, measles, influenza, etc.

Group 3. From biting insects; *e.g.* malaria, typhus fever, plague, trench fever, etc.

The first group, including typhoid and paratyphoid fevers, cholera and dysentery, all of which are intestinal diseases, is largely conveyed from the sick to the well indirectly through contaminated water and food. To develop a disease in this group means that the excreta of somebody who has the disease or who has had it, have been taken into the mouth and swallowed, and the germs finding a favorable medium in the intestines have multiplied and produced the typical symptoms.

The second group, which includes practically all the ordinary diseases like measles, mumps, whooping cough, influenza, pneumonia, scarlet fever, cerebrospinal meningitis, and diphtheria, is conveyed in most cases by one infected person transmitting directly to another person—through coughing, spitting, or sneezing—germs present in the nose and mouth secretions.

The third group is conveyed by insects biting people or animals infected with the disease, and subsequently biting people who are healthy. In this way the disease-producing organism is introduced into the body of the healthy person and there multiplying brings about the symptoms of the disease. Malaria is transmitted in this way by the Anopheles mosquito and typhus fever by lice. Insect borne diseases are greatly to be dreaded in any army because they are so difficult to control.

It is the primary aim of the army medical officer, and particularly of the Sanitary Officer, to prevent the germs of any of these groups from gaining entrance to the body of the healthy soldier and, also, where possible, to destroy them after they have left the bodies of soldiers harboring them. In other words the object of the army sanitarian is to destroy some link in the chain of operations whereby disease germs, discharged by cases or carriers of disease, find their way to healthy soldiers.

To accomplish this in the case of the first group it is necessary to destroy or sterilize all fecal matter which might contain the germs of enteric disease. As this is not humanly possible, it is necessary to protect such fecal matter from flies and other insects which may transmit any disease germs present to food. It is furthermore necessary to protect food from insects, and, since water and milk supplies may, in spite of all existing precautions, become contaminated, to sterilize these by boiling or other equally efficacious means. Wherever we have, as in typhoid fever vaccine, a specific

method of protection, this is invariably employed.

The second group of diseases, including those in which the infective agent is conveyed directly from person to person chiefly in mouth and nose secretions, is practically controlled in armies by early diagnosis, the removal and isolation of the infected cases, and the close supervision of immediate contacts.

Though the work in regard to this group is largely delegated to the responsible medical officer it is the function and the duty of the sanitary officer to see that the purity and safety of the milk and water supplies are ensured and that the drinking utensils of canteens and messes—one of the commonest means of infecting men wholesale—are properly cleansed and sterilized.

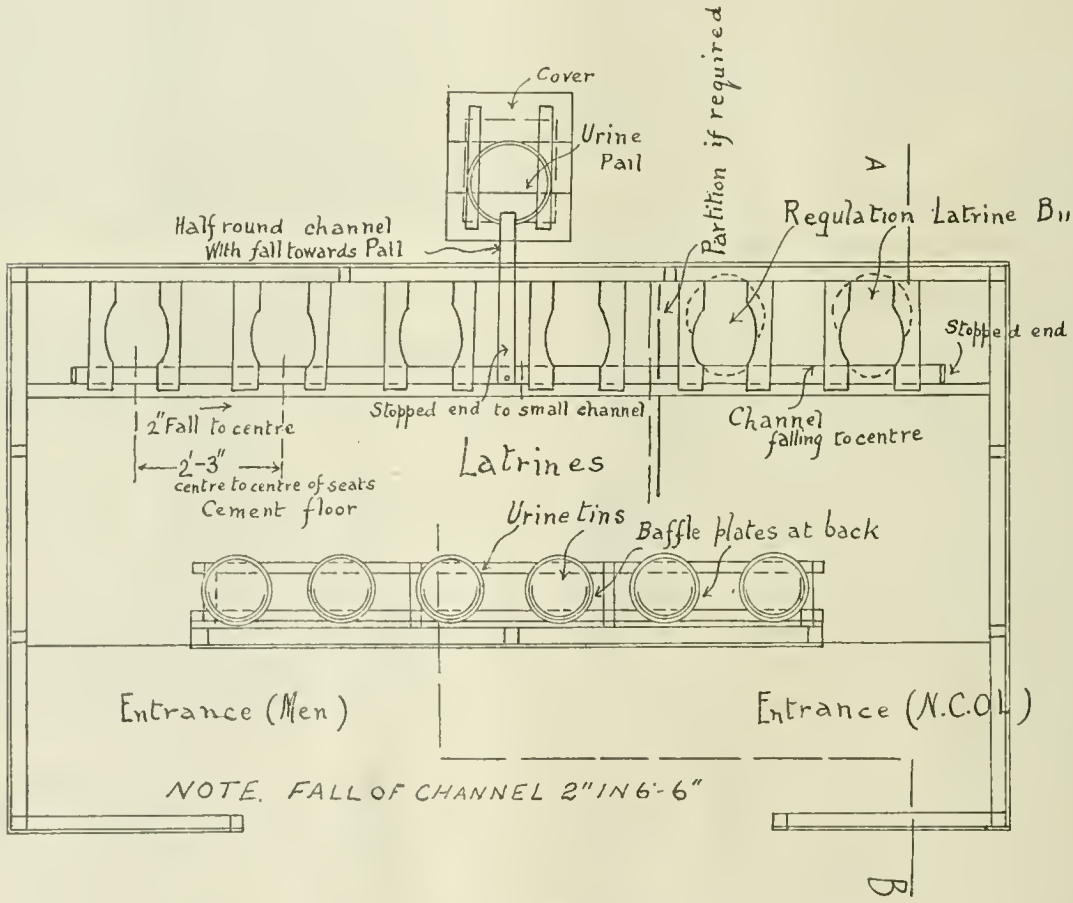

Fig. 1.—Sketch of combined latrine for permanent camp.

The third group of diseases, viz., those conveyed by biting insects, must be controlled through destruction of the insects themselves and their breeding places, as well as preventing infected and uninfected people from being bitten.

In the case of malaria it is good business, where possible to destroy the breeding places of the Anopheles mosquito; it is equally important to remove cases of carriers of the malaria parasite from the army area and to screen the sleeping quarters or even the sleepers in the open air in order to prevent infected mosquitos from transmitting the disease organism; but it is perhaps most important of all to employ the well-known prophylactic—quinine.

In the case of typhus fever, relapsing fever, and trench fever a constant war must be waged against the ubiquitous louse, which transmits the infective agent of each of these diseases; only those who have had experience with an army in Europe know what a continuous and worrisome war that is. Trench fever alone is said to have put more men hors de combat at one time in the British army alone than were present in the original British expeditionary force.

Accepting the above grouping as a working basis it is easy to see how sanitary methods must be adopted to prevent the transmission of disease germs from the infected to the healthy members of the army. Generally speaking it means the rendering of all excreta innocuous, the purification of all drinking water and milk supplies, the control of flying and biting insects, the disinfection of fomites, the early diagnosis and segregation of cases of disease, and the physical cleanliness of the soldier and his surroundings.

Permanent Camp Sanitation.—The sanitary control of permanent camps is a simple matter, particularly when the soldier once realizes that he is an integral part of the sanitary system.

Sewage may be disposed of: (1) By the water carriage system; (2) By the pail system; (3) By the trench system.

In the first case the method is similar to that of any modern town in which sewage is carried by a system of pipes to a disposal system consisting of screens, grit chambers, settling tanks and perhaps oxidizing beds or some modification

it. The effluent from a military camp sewage disposal system should be disinfected.

In the second case the solid and liquid excreta are collected daily in separate pails, and either buried without the camp or destroyed by fire. (See Fig. 1.)

In the third case excreta is received into deep or shallow trenches which are gradually filled in and the excreta finally buried. This method is not suitable or practised in permanent British camps because the area required is too great and the camp ground becomes too much fouled.

In Canadian permanent camps the water carriage system is the one in use; in American permanent camps the same practice usually obtains; in England the method in use depended on the location. On Salisbury plains standing orders forbade the pollution of the ground at all and consequently excreted matter had to be transported miles to districts where it could be buried or utilized as fertilizer.

No matter which of these systems is employed the latrines must be kept scrupulously clean and protected from flies, and disinfectant freely used. In the case of field latrines this fly problem is difficult, yet many ingenious methods have been worked out which have proved quite satisfactory. Crude oil in the pails is useful as a vermifuge and where the excreta are burned aids materially in combustion.

Where incinerators are in use to destroy excreta, it is always necessary to utilize a considerable amount of fuel. In camps and towns the waste paper and other combustible material collected is usually quite adequate but may be supplemented by the use of sawdust or other cheap fuel when available. The intelligence of the men employed at the incinerators and their methods of operation are as important as the fuel supply. In Bailleul, France, incinerators for the destruction of fecal matter were in use not 150 yards from my office in a garden backing up on the same square; yet it was six weeks before I discovered their presence and then through accident. On no occasion was their presence revealed by their odor.

In permanent camps the water supply presents no difficulties. Filtration and disinfection are essential and are almost invariably carried out.

The milk supply is also readily controlled by pasteurization when market milk is used or by the use of condensed milk or milk powder. An outbreak of disease due to a defective milk or water supply in a permanent camp may almost be put down to criminal negligence.

The constant surveillance of army canteens, the thorough cleansing of drinking and eating utensils, and, where possible, the disinfection of the same will do a great deal to prevent the spread of many common communicable diseases.

Control of lice and other vermin is not so difficult in permanent camps where it is possible to insist on frequent bathing. Disinfection of clothing by pressure disinfectors or in special huts heated by steam pipes is also a comparatively simple matter as compared with the handling of the same problems in the field.

Sanitation on Lines of Communication.—When we enter the war zone the problems of sanitation begin to take on a different aspect. At the base we have permanent camps like those at home; yet for the simple reason that nobody can foresee the length of a war or unexpected contingencies that may arise, there is a natural reluctance to expend large sums of money upon sanitary works of a permanent character, particularly in a foreign country. Consequently the tendency is to find sewage disposal works of only a semipermanent character at the base, though the baths, disinfectors, incinerators, and similar apparatus will be plentiful and of the most efficient types.

It must be remembered also that on lines of communication the great proportion of the army will be in billets. Consequently the local means of sewage disposal will serve a large proportion of the military community and will be supplemented only where necessary by additional latrines.

Under these conditions sources of infection through contact with the civilian population, impure water or milk, flies, and fomites will tend to approximate those of civilian life. The great difference between the civilian and army population is that every soldier is encouraged to go to his medical officer at the first symptoms of illness, a practice he is only too willing to avail himself of. Consequently, cases of communicable disease are picked out early and epidemics are nipped in the bud among soldiers, whereas they tend to take their normal course among the civilian population.

For this reason and because it is to the interest of the civilian and army population in warring countries to avoid epidemics, it is the practice for the civilian and military medical men to cooperate and be of the greatest possible use to one another. Thus if a civilian develops diphtheria or typhoid fever or cerebrospinal meningitis in the British army area, it is customary for the civilian medical man to employ the nearest military laboratory for diagnostic purposes and frequently to obtain expert military assistance to give the antiserum or vaccines.

In like fashion it has often been necessary for the British army, in order to protect their own troops billeted in a French town, to chlorinate the local water supply, supervise the local milk supply, assume charge of the sanitation, and even take over the problem of disposing of the contents of middens—no mean task where this is the common method of sewage disposal and consequently where there is one cesspool to every house.

With the British army in France there was comparatively little trouble so far as the French or Belgian authorities were concerned. Local jealousies were easily eliminated by a little tact explaining that the changes suggested would be of real assistance in helping along the Allied cause. It was readily understood by the civilian authority that a soldier was lost to the army and had to be replaced whether the cause was due to a preventable disease or a bullet.

The sanitation of special camps and hospitals on lines of communication was similar to that in base camps. There were no special problems in connection therewith.

Sanitation of an Army in the Field.—In the real

field army the problems of sanitation become more and more difficult of control but here again a great deal of the work is similar to that on lines of communication.

When fighting is stationary or the condition of

Fig. 2.—Incinerator made of petrol tins filled with clay and wired together.

trench warfare exists we have a series of fixed conditions. If we consider the appearance of an open fan we can realize something of the organization of an army. Back at the base of the fan handle we have general headquarters, where the general officer commanding and his staff reside—usually in a town of some size. Farther up on the blades of the fan we have a number of army headquarters. Farther out again are several corps headquarters for each army headquarters; farther out again are a number of divisional headquarters for each corps; still farther toward the periphery are several brigade headquarters for each division; forward still are the battalion headquarters and the front line trench system.

Sanitation in the villages and towns occupied by army headquarters is usually similar to that of towns on lines of communication. As the trenches are approached, however, permanent apparatus gives way more and more to extemporized equipment and field methods. Such field apparatus has usually been evolved through necessity and after much experiment.

Such standard movable equipment as is necessary to the health of the army is invariably cut to the minimum. No more latrine pails will be issued than the number laid down in the book. Iron incinerators can be obtained only with the greatest difficulty because they are heavy to transport and expensive. Consequently the sanitary officer in the field is thrown largely upon his own resources and of necessity has evolved methods and makeshifts that are efficient, are made cheaply from local materials, and can be abandoned without loss when the army moves away. The sanitation of the army in the field gives great scope to the ingenuity of the sanitary officer; it is the type of sanitation that is of the greatest interest to the civilian sanitarian versed in the general principles of hygiene and sanitation.

The sanitary methods in use in the town of Bailleul in Northern France, close to the Belgian border, will serve as an illustration of those found in other towns and villages in the war zone on the Western front. Bailleul was the headquarters of an army corps. In peace times it had a normal population of about 12,000, which increased to about 18,000 during war. There was no water-carriage system of sewage, each house having its own cesspool. The water supply was piped from Mt. Rouge, about three miles away, where it was collected in a series of galleries and wells sunk in the hillside. In the town a standpipe holding some 18,000 gallons served to equalize the supply and maintain pressure.

The sanitation of this town was taken over by the British army. Instead of muddy and littered roads and streets, the latter were swept daily and kept spotless. The rubbish, such as paper, cardboard, wood, straw, and other combustible

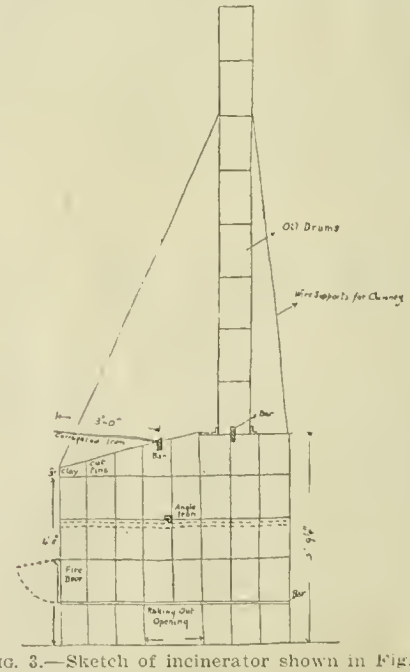

Fig. 3.—Sketch of incinerator shown in Fig. 2.

material, was used as fuel at the numerous incinerators constructed by the army sanitary officers on the edge of the town. Mud and other non-combustible matter was carried to a dump in the adjacent countryside. Horse manure,

of which there was a large quantity, was carted to special incinerators adjacent to the battery of smaller incinerators on the outskirts of the town, and burned. Even the cesspools were emptied under army supervision, by means of a mobile gaso-

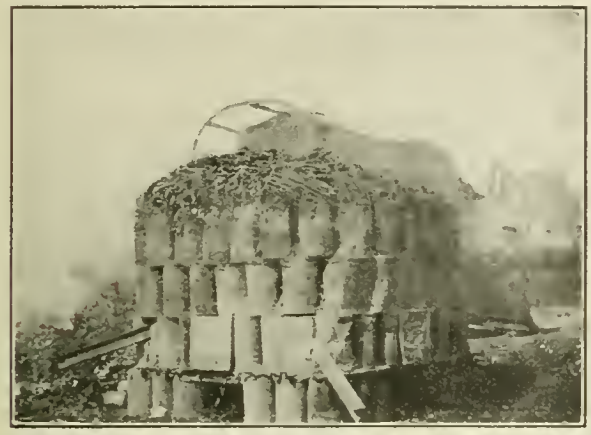

Fig. 4.—Incinerator for destruction of horse manure.

line engine, pump, fire hose and barrels, and the liquid carted away to the farms to be utilized as fertilizer.

Special latrines (Fig. 1) were constructed in different parts of the town for the use of the military only; these were always placed where considerable bodies of soldiers were stationed, as, for example, at the headquarters of an army supply column. In order that the excreta need not be carted through the town and for the sake of conservation of labor, incinerators for the burning of this excreta were built beside these latrines. The combustible material was also brought to the same points, and, as a liberal amount of sawdust was also available, the British soldier found little difficulty in operating these incinerators satisfactorily and without odor right in the heart of the town. In this way the problem of operating latrines, the disposal of excreta by incineration, the disposal of garbage, and economy of transport and labor was satisfactorily solved by a little common sense.

On the edge of Bailleul, near the railway station, a battery of home-made incinerators was constructed from plans elaborated by the British sanitary officer of the town. (See Figs. 2 and 3.) The country soil of Flanders is a heavy, tenacious clay. This sanitary officer discovered that a mixture of this clay and the ash from garbage, when burned, formed a stonelike concrete. He employed 5-gal. rectangular gasoline tins filled with this mixture as bricks with which to construct his incinerators, the cans being wired together with old wire from bales of hay, as shown in the illustration. Fire doors and ash doors were made of tins beaten flat. Old pipes, iron, rods, bayonets, or other scrap were used as grates to support the garbage, and the top was also built of flattened tins wired together. A partition built inside in such a way as to force all smoke through the bed of burning material did not allow of the escape of incompletely burned gases, and consequently there was practically no odor from this cause. The chimney was built of round oil tins with the ends cut out, fitted together and wired.

When the fire was started with rubbish the whole affair baked like stone, and, as the spaces between the tins were plastered with the puddled mixture of clay and ash the incinerator became practically a solid block of stone. The proof of the pudding is in the eating and when I first saw these incinerators in operation they were working perfectly and continued to operate as long as the army occupied the town.

These small units were used chiefly to burn fecal matter and garbage. Close at hand larger units were built for the destruction of horse manure (Figs. 4 and 5). These incinerators were built of gasoline tins or oil drums filled with the clay mixture, in the form of large cylinders about twelve feet in diameter eight feet high, and with open tops. The tins were loosely wired together so that a long iron rod could be inserted between them to stir up the fire and shake down the ashes. The grate bars employed to carry the tons of wet manure and garbage were pieces of old pipe or angle iron, and several pieces were also run at various angles across the incinerator higher up to distribute the great weight of material. When these incinerators once got under way there would be a glowing mass of incandescent material three or four feet deep at the bottom, surmounted by a zone of partially cooked material. On the top was the wet mass, which slowly dried out from the heat beneath. By judicious stoking through the numerous chinks between the drums the dried material was forced down and the fire kept steadily burning. In the evening these incinerators were piled high with refuse, which dried out to a considerable extent during the night, and burned rapidly when stirred up in the morning.

Of course there was a secret in connection with the successful combustion of fecal matter, gar-

bage, and manure, all of which was wet and tended to cake. Caking effectively prevented air and gases from getting through the mass and bringing about combustion. The great secret consisted in mixing large quantities of bully-beef and jam tins with the wet material to be burned. As the combustible material dried it separated from these tins, which also collapsed, with the result that innumerable air spaces formed throughout the mass, allowing a free circulation of air and gases and forming a friable mass which could be poked down with the greatest ease as it dried out.

The tins and clinkers from these incinerators were employed to build roads around the incinerators and make them easier of access.

The water supply of the town was of a yellowish tint and after heavy rains somewhat turbid, with occasionally high bacteria counts and *B. Coli* present in one cubic centimetre under the same circumstances. The water was examined daily in the local mobile laboratory of the British army and in consequence it was considered advisable to chlorinate the water supply. This was done by allowing a regulated amount of hypochlorite of lime solution to flow into the stream of water entering the water tower, a procedure that proved to be quite satisfactory.

The net result was that this particular town was kept clean and free from flies; the water supply was made perfectly safe; the sewage problem was solved most satisfactorily, and in general the inhabitants were never so thoroughly protected from disease as during the time of the British occupation. Furthermore the army laboratory was at the disposal of the local physician for diagnostic purposes and its personnel was availble for taking blood cultures, throat cultures, or giving vaccines or sera.

About seven miles from this typical French town with its typical problems of sanitation were the front line trenches. In this seven mile area were a few little villages and hamlets with extensive army iron-covered huts, built usually in close proximity to the more or less shattered villages. The intact buildings in many of the towns and the immediate neighborhoods served as quarters for the various divisional staffs, for hospitals and other purposes. This area back of the trenches proper was occupied by the artillery, engineers, army service corps, ammunition columns, labor battalions, and all the non-combatant units essential to carrying on the work of an army in the field. Every farmhouse, barn, and cellar was in constant use by some section of the army. Shelter from the elements was at a premium and any shelter is better than no shelter. Consequently in this forward area there were numerous single billets as well as villages, hutments, field hospitals, and other groups to be looked after.

The British army regulations are such that each officer and man must be a sanitarian and must not only observe the regulations but see that others do the same; the principle underlying this system being that "if each before his doorstep swept, the village would be cleaner."

There is in each division of approximately 20,000 men, a sanitary section, composed of one officer and 25 men, whose function it is to keep an eye on the sanitation of the divisional area, report failure on the part of units to observe the established sanitary regulations, see that the incinerators are operated, have new sources of drinking water tested, look after the bath houses, search for cases of communicable disease among the civilian population, and, in general make itself as useful as possible in protecting the army from disease.

It is not the duty of the sanitary section actually to keep the divisional area clean, but rather to see that those responsible keep it clean. In this way every man is made a responsible party, and if the officers of any unit see that the regulations are enforced by each man, the unit as a whole will be a sanitary one.

Besides the sanitary officer of each division there is a sanitary officer for each army, and a chief sanitary officer for the whole expeditionary force. These are all in touch with the sanitary adviser at the base and the authorities in England. Since, under war conditions, new developments are always taking place in this work, any knowledge gained that may be of practical value filters through to the army by these channels as well as through the scientific journals.

In the army in the field the group of intestinal diseases referred to at the beginning of this article is kept under control by the following means: (1) Inoculation of all troops against typhoid and paratyphoid fevers. (2) The destruction of all excreta by fire, or rendering it innocuous by burial. (3) The chlorination—and usually clarification or filtration—of all drinking water. (4) The protection of latrines and food supplies from insects. (5) The search for carriers in cases of suspicious outbreaks.

1. Over 97 per cent of the British army submitted voluntarily to inoculation against typhoid and paratyphoid fevers; the others usually came to it after a few weeks in the field. This, of course, constitutes the first and strongest line of defense, since when other sanitary precautions fail, as they must fail under certain periods of advance or retreat, the inoculated individual carries about with him in his own body the specific preventative. Naturally inoculation with triple vaccine rendered the diagnostic agglutination reaction for typhoid or paratyphoid fever almost useless.

2. *Destruction of Excreta.*—The incineration of fecal matter was carried out to a considerable extent in the field, where extra fuel supplies were available. To a large extent, however, the deep or shallow trench had to be utilized, deep trenching being favored, since it attracted flies less and reduced the area of ground necessary. Petroleum was usually available as a fly repellent.

Where the pail system was employed many ingenious methods were devised and used to cover the pail and make it fly proof. A collection of models of these and other sanitary devices was made by one sanitary officer and placed on exhibition in a front line town, and all medical, sanitary, and other officers in the surrounding area likely to be interested were invited to visit the exhibition. In this way the ideas of the ingenious men were handed on to others perhaps

seeking the solution of some local sanitary problem, which had already been solved by one of the methods exhibited (Fig. 6).

In the trenches the pail system was used; the latrines were established in separate trenches, the pails were carried back at night by fatigue parties and the contents buried, frequently in some convenient shell hole.

Garbage, wherever it was practicable, was burned rather than buried.

Frequently instead of collecting solid fecal matter and urine separately the solid material only was collected; the liquid in such cases where the soil was suitable would pass from the improvised urinals into deep soak pits which had been filled with stone, brick or other loose material (Fig. 7).

Sullage water was also handled in similar soak pits. As, is well known, the ground in the neighborhood of a kitchen or wash bench soon becomes impervious if soapy and greasy water is constantly thrown upon it. It is therefore absolutely necessary to arrange sullage pits in such a way that the greater part of the grease is collected on some loose combustible material before it reaches the soak pit proper. This was successfully accomplished by allowing the sullage water to trickle slowly through an elongated box stuffed full of twigs, straw, grass, or other loose fibrous substance. The grease stuck to the filling material, which was taken out daily and burned. The sullage pit could then readily handle the grease-free water, and was capable of being operated for prolonged, sometimes astonishingly long, periods, without plugging (Fig. 8).

3. *Water Supply.*—In the British army it is the custom to assume that all water supplies are contaminated—a pretty safe assumption in Europe. At the beginning of the war the British two-wheeled water carts, which are barrel-shaped and underslung, were equipped with two clarifiers, one on either side of the body and above the wheels. Each wagon was equipped with a force pump and a length of hose to be introduced into the raw water supply. When the hand-pump was operated the raw water passed through a layer of alum, some of which was dissolved, forming a flock. This flock passed into a hollow cylinder around the ribs of which was tightly wrapped a length of special canvas. The canvas was long enough to pass around the cylinder several times and was tied on with tapes.

The scheme was such that the raw water with its entangled flock had to pass from the outer cylinder through the canvas to the inner cylinder and thence into the water cart. No water was allowed to pass into the cart until the first of the clarified water issuing from a by-pass was seen to be clear. Where the water supply was reasonably clear the clarifier was not employed. In practice the pressure on the canvas frequently became so great where a water was very turbid, that the metal ribs caved in and rendered the apparatus useless. At the beginning of the war the clarifiers were attached to the pump and the body of the cart by fixed metal connections which tended to break, but this defect was readily corrected by substituting rubber pressure hose and placing a single clarifier on the front of the water cart.

Under all circumstances, whether the water was clarified or not, standing orders called for the addition of chloride of lime as a disinfectant. This was supplied in quarter-pound tins with a small spoon attached to the inside of the cover. One or more heaping spoonfuls of the chloride of lime were added to the water in the cart when partly filled: the addition of the rest of the water and the agitation that occurred as the cart was driven back to its station usually proved sufficient to mix the dry powder intimately with the

water and bring about the desired result. Frequently, of course, the water was overdosed or underdosed. In the former case the men refused to drink the water and the matter would be corrected. Failure to add a sufficient quantity was not so easy a matter to correct.

FIG. 7.—Disposal of urine when solid material only is collected.

Early in 1915 the Canadian mobile laboratory attached to the British army initiated the practice of taking samples from the water carts preferably shortly after they had been filled. Tests made on the spot with soluble starch solution and potassium iodide revealed the presence or absence of the slight excess of available chloride necessary to bring about satisfactory disinfection. Bacteriological samples taken at the same time proved conclusively whether the water had been treated with hypochlorite of lime or not. Absence of *B. coli* in one cubic centimeter and a low bacteria count was, after some preliminary work, taken as almost certain evidence of treatment; while high bacteria counts and presence of *B. coli* was found to indicate no treatment. These bacteriological findings were reported to the Director of Medical Service of the army and the Assistant Director of Medical Service of the division concerned, a procedure that proved most gratifying in improving the safety of the water supply. The failure was placed on the responsible parties, and where it was necessary every assistance was given by the laboratory to fix the amount of disinfectant to be used, without causing a taste and yet sterilize the water. This was not so difficult as might be imagined, for in any given area there was a comparatively small number of approved sources used for obtaining water. The men in charge would go only to places where the supply could be counted on as plentiful, and these finally became fixed approved sources.

In 1915 an outfit was issued by the sanitary department of the war office to go with each water cart. This outfit enabled the water "detail" to test for himself the actual amount of disinfectant to be used, but in practice it was found that only the interested, intelligent men ever took the trouble to understand the method, which was simple enough. The apparatus consisted of a series of glass tumblers arranged in a row. Each was filled with the water to be tested. To the first was added one drop of a standard solution of chloride of lime made up according to formula; to the second two drops were added, and so on to the sixth. After fifteen minutes solutions of potassium iodide, soluble starch, and sulphuric acid were added to the glasses in turn and mixed with a glass rod. The glass which just showed the blue coloration was taken to be the one desired. Thus if it happened to be the third glass, that is the one to which three drops of the hypochlorite solution had been added, it meant that three of the standard spoonfuls of dry hypochlorite of lime were to be added to the water cart. If it turned out to be glass No. 1, then one spoonful was indicated.

Control of the water supply by the laboratory proved to be a very satisfactory procedure and was adopted throughout the British army. Not infrequently a new division would come into the

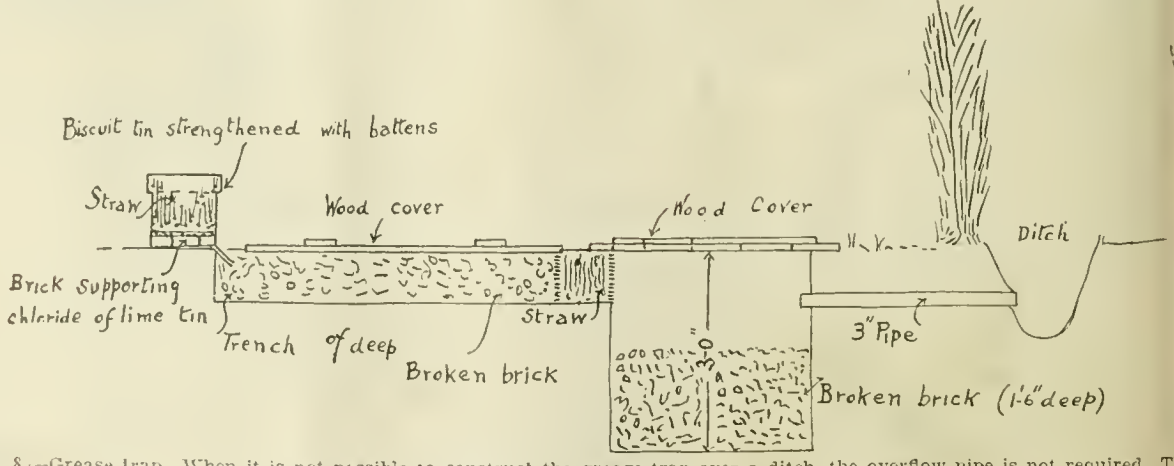

FIG. 8.—Grease trap. When it is not possible to construct the grease trap over a ditch, the overflow pipe is not required. The water in the pit should be baled out and scattered over cultivated land.

area and we would find perhaps only twenty-five per cent. of the water carts being treated by the hypochlorite solution. After two or three weeks, during which the medical and sanitary officers had had their attention drawn to their failures, we would find perhaps ninety per cent. of the water carts being treated satisfactorily. Not only so, but the men would become really interested, realizing that it was responsible work, which, if neglected, meant sickness and consequent inefficiency. When a water detail once grasped intelligently the reason why he was called upon to do his work, he never went back to his careless methods. It was only lack of knowledge and training that made these men inefficient. As an example of what I mean, the first Canadian division water details were thoroughly trained in Canada and in England. No matter where or when we happened to take samples from the water carts of that Canadian division in France, the samples were almost invariably sterile. The men had learned the why and wherefore of their job and took as much pride in it as the infantry man takes in looking after his rifle.

At some water supply centers the chlorination of the water in the carts was not left to the discretion of the individual, but he was told how much hypochlorite of lime to add. Personally, we thought this to be a mistake, for it took all responsibility from the individual and to some extent must have spoiled him for the periods when he would be thrown entirely upon his own resources.

The method of disinfecting small quantities of water by means of a solution of hypochlorite of lime was devised by Nasmith and Graham, and published in the *British Army Medical Journal* in 1911. This method, applicable to a pail, a barrel, or a cart full of water was used to a considerable extent, by the Canadians, particularly. Since the apparatus required consisted of a spoon and a cup only, the method was of universal practicability. Frequently in the trenches and close to them, casks or tubs were set up and the water in them disinfected by the process, where the employment of the dry powder would have been impossible.

The suggestion to use the dry powder was made by prof. Sims Woodhead about the same time. Tiny tablets of hypochlorite of lime, each sufficient to sterilize a pail of water, were made at the writer's suggestion and issued to Canadian units, such as cavalry which might at times be compelled to operate far afield. These were not generally employed and their issue was subsequently discontinued.

In 1914, before leaving Canada for the war zone, the writer had plans draughted of a mobile water purification filtration unit. This unit was to consist of a gasoline engine, pump, sand filter, and disinfecting apparatus, all mounted on a heavy motor lorry. Early in 1915, as a result of experience in France, a paper was published in the *British Army Medical Journal* calling attention to the necessity of such a mobile filter unit in France. The Toronto firm by whom the plans had been draughted for the writer had, meanwhile, through its London branch, drawn the attention of the War Office to duplicate plans which had been forwarded from Canada.

The principle of the water purification unit was accepted by the War Office and several makes were built and forwarded to France during the summer of 1916. Barges with the same type of equipment, but on a larger scale, were also sent to France and to Mesopotamia, where they proved particularly valuable.

The necessity of such mobile filter units was made apparent from the fact that any stream, pond, canal, or other copious supply could be employed for drinking purposes after it had gone through the purification unit. The original idea was to connect one or more of these units with tank lorries or standpipes, at which the ordinary water carts could fill with sterilized water, while the units could, if necessary, go on operating night and day. The lorry filter units worked quite satisfactorily. The barge filter units were even better. Two of these frequently examined by the writer were situated on the Lys River behind Armentières. They were connected to a tank barge into which passed the filtered sterilized water. Gasoline engines and pumps on shore drew the water from the tank barge and forced it through pipes into a series of elevated tanks situated within a radius of three miles of the filter barges. At these tanks the water carts were filled with the purified water.

It is of interest to note that this mobile filter unit was adopted by the American army after thorough investigation—a sufficient proof that the method had proved to be the last word on the subject.

The problem of getting safe water in the front line trenches was not always an easy one. At night the water carts were brought up as close as possible, and fatigue parties from the trenches went back with water bottles and dixies to be filled. In other places, again, it was possible to utilize wells in the neighborhood of the trenches and obtain a more or less precarious supply at night. One of these was responsible for a small but acute attack of pseudo-dysentery. In other places water was brought up on the light railways which came into use more and more as the war kept on. In other areas it was brought up through pipes.

While digging new trenches "springs" were constantly being discovered and were always hailed with delight locally. These "springs" were almost always badly contaminated and were usually condemned. One of these was found in the laboratory to have a bacteria count of hundreds of thousands of bacteria per cubic centimeter. It was condemned on general principles and later on was found to issue from ground in which sixty Germans had been buried. Near another section of trench a shell exploded, uncarthing a "sewer," which was really part of the ordinary subsoil drainage system of the countryside, and the water, of course, was partially filtered surface water.

During an advance in so far as possible the same system was kept up; that is, water carts followed up the advancing battalions and were so placed that fatigue parties could obtain the necessary water supply. In some cases the extension of water pipe lines followed the advance by only a few hours. Of course, many men drank water from shell holes or other convenient supply and took chances on contracting disease.

During the capture of the Messines-Wytschaete ridge by the British, many hundreds of cases of true dysentery, of both Flexner and Shiga types, developed among the attacking British soldiers, but without a single death occurring. They had the specific protection against typhoid and paratyphoid fevers, but, of course, no specific protection against dysentery. The epidemic was quickly stamped out.

To demonstrate that freedom from intestinal diseases is not due to accident, a single example will suffice. Early in the war, when the British took over from the French a section of line in the Ypres salient, the Belgian population in the little village of Vlamertinge and surrounding country was devastated with typhoid fever, and there were also many cases of the disease among the French troops. When the British troops took over the area they not only escaped contracting the typhoid fever themselves, but they succeeded in absolutely stamping it out from among the civilian population, and also in getting rid of any "carriers" of the disease. So completely was this disease eliminated that during the last six months of my stay in that area a civilian search party, composed of non-combatant Quakers, failed to discover a single case, though they carefully and persistently carried on a house-to-house campaign in that district in a search for cases of epidemic disease.

No cases of cholera occurred on the Western front, but they did occur in the Serbian, Russian, Austrian, and German armies. The methods of dissemination and control are similar to those of typhoid fever.

True bacillary dysentery was rare on the Western front and usually developed in units which had been in the Near Eastern front, Egypt or India. It rarely spread further. Amebic dysentery also occurred among the same units to a limited extent.

In the army in Gallipoli dysenteries of both types were very common and played havoc with the force. It was impossible to build fires or destroy excreta on the Gallipoli peninsula; there was no space or fuel, and the trenches were under direct observation. Flies abounded, and swarmed over everything: the connection between food, flies, and feces was too direct to merit more than passing mention. Practically everybody in the Gallipoli expeditionary force got some intestinal disorder, ranging from the mildest form of diarrhea to the types which proved rapidly fatal. Among the diseases contracted there was one which was not clearly diagnosed at the time because hospital and laboratory research facilities were not available in the area, but which was probably epidemic jaundice, or Weil's disease.

Weil's disease was diagnosed bacteriologically in the Ypres region for the first time in 1916. The Japanese had recently proved that epidemic jaundice and Weil's disease were in all probability identical: the causative agent was proved by them to be a spirochete which could multiply in water and could pass through the unbroken human skin. It is of interest to note that the spot where the half-dozen cases came from in the Ypres region in Belgium was a place where a small stream came through from the German lines.

4. *The Control of Flies.*—A great deal of effort was made to control house flies by destroying their breeding places. Manure was burned, buried, scattered on the land, covered with earth, soaked with various chemicals, and surrounded with traps, but flies persisted. In the front line a blue variety of fly, which seemed to breed everywhere outside of manure piles, caused as much or more trouble than the regulation house fly, and nothing could be done to control it.

In the areas occupied by civilian French or Belgians each farmhouse was a center for the propagation of flies, for each country house is literally built around a gigantic manure pile. Manure in France means wealth, the crops obtained depending literally on the amount of manure used as fertilizer. As a consequence every bit of household waste, as well as manure, is tossed into the gigantic manure pit occupying the courtyard, around which are assembled the house, barns, cattle and pig pens. It is little wonder then that when it came to the question of destroying these manure piles the British army found itself up against an impossible situation and had to compromise. Various sprays, which would destroy fly larvæ without affecting the fertilizing value of the manure were tried out, with but very limited success, and the control of the breeding places of flies never was realized. In the Near East and Egypt the flies were a real menace and undoubtedly responsible for much disease.

Though food supplies were usually well protected when received, many possibilities of fly contamination made protective measures sometimes seem almost hopeless. For example, one hot summer day the writer saw a unit of a famous Highland Division getting the midday meal. A rough table had been built at the end of a beautiful orchard. At the other end of the orchard were the latrines. As we chatted to the officers I noticed men going to the latrines and returning. Each one was accompanied by a considerable number of flies, and a large number of flies also hovered about the food being placed on the table. The possibilities were obvious, yet the writer believes from the wonderful record of the British Army in France in freedom from enteric diseases, as well as from personal observation, that flies played a very small part in the transmission of disease. Elsewhere the story was different.

5. *Carriers.*—Whenever there was any reason to suspect an outbreak of typhoid, dysentery, or other disease, the services of the mobile laboratory staff in the area were requisitioned and an attempt was made to discover the origin of the epidemic or possible epidemic. The cooks and immediate companions would be questioned closely and possible samples of excreta taken for examination in the laboratory in the attempt to discover "carriers." The water supply, food supply, and other possibilities would be examined also, in an endeavor to locate the trouble. A considerable number of the not numerous, epidemics of diarrhea were found to be due to a change of food and would clear up in a day or two. The Maconachie ration, which was a sort of Irish stew, was quite frequently blamed by the medical officers for this type of diarrhea.

In the British Army the use of unboiled milk and uncooked vegetables was absolutely prohibited.

The tragic death of General Maude from cholera

in the midst of his great success against the Turks, said to have been due to a single drink of unsterilized water, is a startling example of what one lapse in the usual sanitary precautions can accomplish.

Amebic dysentery caused much trouble in the armies along the Mediterranean. A great deal of research in England established the fact that in the resisting stage the *Entamœba histolytica* was capable of standing the drouth and heat of the Sahara desert for many months and yet be capable of transmitting the disease to animals. The obvious and only known method of controlling this disease at present, therefore, appears to be the incineration of all fecal matter. The cure is long, painful, and problematical at best, though emetine is said to be a specific cure. The horror of emetine by men who have taken that course of treatment is remarkable.

Hookworm disease does not seem to have developed at all in the British armies on the Mediterranean seaboard.

Diseases Conveyed by Direct Contact.—Of these diseases there is little to be said from the sanitary standpoint, the general methods of control outlined at the beginning of this article being much the same as in civilian practice.

Men returning from leave were always introducing measles, mumps, or other contagious disease, but they seldom established themselves in epidemic form. Early diagnosis and removal of the case and observation and isolation of contacts was usually sufficient to prevent their further spread. It was interesting to note that the men of the Highland divisions, recruited from the glens of Scotland, and the Maoris from New Zealand showed very little resistance to the ordinary children's diseases. These two races had evidently little specific immunity, either transmitted or acquired, and were far more liable to contract and become seriously ill from these diseases than ordinary troops. Measles made the Maori very ill indeed, while we had a very difficult time stamping out diphtheria from a Highland division. Many of the men picked out and isolated as diphtheria carriers subsequently came down with the disease; incidentally, one brigade was reinfected by men returning from hospital still carrying diphtheria bacilli.

Cerebrospinal meningitis never became epidemic in France, though isolated cases cropped up at irregular intervals. Smallpox, that curse of past centuries, was kept in absolute subjection by vaccination.

Diseases Conveyed by Biting Insects.—As far as the warring armies in Europe were concerned, the diseases transmitted through the bites of insects comprised only malaria, relapsing fever, typhus fever, trench fever, and bubonic plague. What further diseases of this group may have occurred in Egypt and Asia Minor we have little specific knowledge of, for nothing has apparently been published on the subject.

Of these diseases trench fever was responsible for the greatest number of casualties in France among the British and French armies. In the Italian and Grecian war theater, malaria exacted a heavy toll, while in Serbia and Russia typhus fever was perhaps the most devastating of the insect-borne diseases. Statistics along this line are not available and probably have not been compiled.

The story of Serbia, as the writer heard it from the Serbian representative at the meeting of the War Allies Sanitary Commission in Paris in the spring of 1916, was intensely interesting from the standpoint of the sanitarian. When the German army overran Serbia the whole of the civilian population retreated with the Serbian army. The retreat occurred in the depth of winter and any billets had to be divided between the civilians and the army. Nearly all the medical and sanitary equipment was lost. There was no hospital accommodation. Whatever diseases the civilian population happened to be infected with they gave to the army; whatever troubles the soldiers had they transmitted to the civilians. The misery and suffering was indescribable, and when the retreat finally ended the condition of the Serbian army and the people was pitiable in the extreme. From famine, exhaustion, and disease it is supposed that about half a million Serbs perished and the remnants of the army for many months, through physical exhaustion, were absolutely worthless.

It was the American commission which evolved order out of chaos and established an efficient medical and sanitary service. So bad were the conditions that hospitals endeavoring to take only typhoid fever, for example, would find cases of influenza, relapsing fever, typhus fever, and almost everything else developing in the wards. It was literally an era of famine and pestilence for the Serbs, and the damage done by disease was infinitely greater than that accomplished by the armies of the enemy.

It is a classic example of what may happen to a modern army and to a community of our own day when all sanitary precautions and equipment are swept away and disease as a consequence obtains the upper hand.

The freedom from lice-borne diseases—except trench fever—on the Western front is therefore all the more remarkable, since lice are omnipresent in all armies. The control of typhus fever, relapsing fever, and trench fever depends on the control of lice; that is, it is largely a question of personal cleanliness. People who take frequent baths with soap and water do not carry lice; those who do not bathe, sooner or later will become lousy. Since typhus fever has always been recognized as a great army scourge, steps were taken at once by the British and French authorities to insist on their armies taking regular baths. When trench warfare had once become established this was a comparatively simple matter. Bath houses were established in breweries or special shacks constructed for the purpose in every divisional area, and were sufficient in number to enable every soldier to get a bath whenever he came back into billets. If the bath houses were in breweries the large beer barrels were cut in two for baths. These were filled with cold water and live steam turned into the water to warm it.

Most of the bath houses were in shacks built upon the edge of creeks or ponds and the water was heated by some kind of boiler, frequently of the threshing machine type. One section of the

shack was usually divided off for a bathing room with a number of showers and the other rooms were devoted to the receiving of dirty clothing, washing, drying, and sterilizing. When the men in groups of twenty or thirty at a time passed into the first room they undressed and their dirty underclothes, socks, and shirts were thrown to one side to be washed. The uniforms were hung on numbered racks and hung in the disinfection chamber, where they were immediately treated with live steam, or taken into an adjoining room, where the seams were ironed with hot irons to destroy lice and their eggs.

As the men passed out from their hot bath through another room they were given clean socks, underclothes, and shirts, and by the time they were dressed in these their own uniforms, disinfected, were handed back to them. The whole operation took approximately half an hour and from 1200 to 1500 men, on an average, passed through each bath house in a day.

The discarded clothes were washed and mended by the local peasant women, paid by the army. In one of these establishments which I had occasion to visit there were 160 Belgian women constantly employed. Socks and clothing too far gone to be mended were packed in bundles and sent back to the base.

Unfortunately, the soldiers returning to the trenches or to billets clean and free from vermin soon became reinfected from lice present in the billets or dugouts, and they were soon as lousy as ever. It was difficult to keep the men supplied with disinfected blankets and consequently these were sure to be a source of infection. However, speaking broadly, the British army succeeded in destroying most of their lice at least every three weeks.

No typhus fever developed in the British army on the Western front, nor a single case of relapsing fever. Cases of relapsing fever did occur in Gallipoli and Egypt to a limited number.

Trench fever, casually proved early in 1915 to be carried by lice and confirmed by American workers recently, has been a real scourge to the Allied armies. Tens of thousands of soldiers were rendered hors de combat for from two to many weeks at a time, and although it was not a killing disease it was responsible for making ineffective the equivalent of whole army divisions at a time. More frequent baths which would destroy the period of incubation necessary in trench fever would probably eradicate the disease very quickly, but the exigencies of war did not permit of this.

The waste wash water from the baths and laundries entering the creeks and ponds naturally caused a lot of trouble. Horses will not drink soapy water and brewers objected to using it for brewing.

Consequently this waste water was usually treated in tanks with an excess of chloride of lime which precipitated the soap as a curd and carried the dirt down with it. By sedimentation and filtration through sacking, cinders and sand, the water was clarified and flowed into the creeks clean.

One bath house, situated on a pond which formed in the wet months and had no auxiliary source of supply in creeks or springs, was operated during the whole of the year on this limited supply though a thousand men were bathed a day. The wash and laundry water was collected and treated with a slight excess of acid to remove the grease, which floated to the surface with entangled dirt. This scum was filtered off through old sacking, laid over ashes and sand. Any excess of acid was neutralized with lime and any excess of lime removed by soda. The filtered water which was finally turned back into the pond was as clean as ever and yet with sufficient softness to form a lather with soap.

Bubonic plague has not existed in epidemic form among the warring nations in Europe. Fleas did not seem to be common among the men in the British army; rats were plentiful in all the trench systems of all the armies and acted as quite efficient scavengers in cleaning up odds and ends of food. A desultory warfare was maintained against them in the British army, but no organized effort to destroy them in large numbers was attempted. The French sanitary authorities made more strenuous efforts to destroy rats by means of a vegetable poison with results stated to be satisfactory. Had bubonic plague occurred there would doubtless have been thorough attempts made to eradicate the rat.

Malaria in France was comparatively unknown though the Anopheles mosquito is ubiquitous. There were, however, numerous cases of malaria recurring in soldiers from India, Egypt, and other tropical countries. We therefore had in France a fair number of infected individuals carrying the plasmodium of malaria in their blood, as well as the variety of mosquito capable of transmitting the same from man to man. Yet we had in 1915 not more than a dozen cases of malaria develop in men who had never been out of England, and were, therefore, presumably infected in France.

In the armies of the Near East and in Egypt it was quite a different story, a considerable number of cases of malaria developing in spite of attempted prophylaxis by means of quinine.

The control of the spread of Acari in the army is always difficult and the usual numbers of infected men were found. In some cases the curative treatment necessary for bad cases required several months.

In the first winter of the war "trench foot" was the cause of a great number of casualties. Trench foot was due to a combination of cold, wet, and lack of exercise, and occurred among men who had to stand immovable for hours at a stretch in the icy water and mud of the trenches. Various degrees of the trouble occurred, ranging from a sort of glorified chilblain to a condition of the feet where gangrene set in and amputation or even death resulted therefrom. It was soon discovered that a routine consisting of the periodical removal of puttees, drying and chafing the feet and legs, covering them with whale oil, and putting on dry socks was an absolute preventive, and it became a crime for a man to get trench feet or for an officer to let his men get them. With the issue of rubber "waders" and the adoption of the above routine, trench foot disappeared from the British army.

When the medical history of the war comes to be written, it will probably be found that on the Western front the incidence of and mortality from the common civilian diseases was little if at all higher than in civilian life. It will also probably be shown that trench fever, which was not taken very seriously because it was a non-killing disease, was the greatest disease factor in producing inefficiency in the army.

With the exception of those occurring in Russia and Serbia, no great epidemics have as yet followed as a result of the presence of war, similar to those which have been associated with all the other great wars of history. It is to be expected that the toll from preventable diseases which must now be devastating Russia as a result of her disorganization will prove to be of great proportions. We have to look no farther than our own country to see how terrible are the effects of a disease like influenza, for which we have no specific cure and little knowledge of how to prevent its spread. It gives us some slight conception of what would have occurred in the world had we no control of the diseases which formerly scourged humanity and which particularly during and after war wiped out millions of people.

The record of the western world to-day in its comparative freedom from pestilence is a magnificent tribute to the work of the medical profession and an extraordinary indication of the advances which have been made in preventive medicine during the past few decades. The work of the medical profession in the armies of the Allies has been marvelously efficient in controlling the spread of communicable disease. No less efficient has been the wonderful work of the quarantine services of the allied countries, particularly on the Mediterranean seaboard—work performed so efficiently that none of the diseases common to the countries of the Near East ever gained a foothold in France. No pen at the present time can do adequate justice to a theme of this sort. Only the medical historian of the future with the complete facts at his disposal will be able to tell the story of how disease was conquered—a story which will be scarcely less interesting than that of the war itself.

41 Oriole Road.

Military Medical News.

Men in Army Hospitals.—According to statistics published by the War Department there were 56,979 military patients under treatment in army hospitals in this country on April 8. Of this total, 38,214 were men from overseas.

Deaths of Dental Officers.—Casualties in the Dental Corps of the army, tabulated by the Surgeon General's office, show that six dental officers of the corps were killed in action and 47 others died of disease while in the service.

Concentrating Army Hospitals.—Surgeon General Ireland has issued an order that the patients of all army hospitals be concentrated in as few wards as possible. The object of this order is that the personnel of the army hospitals may be reduced to the minimum consistent with efficient operation.

Health of the United States Troops.—The Surgeon General's office announces a continued decline in the prevalence of serious diseases among the United States troops, both at home and abroad, for the week ended April 4. The death rate from disease for this week dropped from 7.9 a thousand for the previous week to 7.5, and in the overseas forces from 7 to 5.

German Dead in War.—Official figures of German losses during the war have been published by Dr. Rubner Privy Councillor of Prussia, according to which the number of soldiers killed outright or who died of wounds was 1,486,952 and those dying of sickness numbered 134,081. The total number of civilians who died from sickness said to be due to malnutrition is placed at 562,769.

Col. George Crile, M.C., U. S. Army has received a medal from the United States Government in recognition of his services and leadership in medicine and surgery during the war.

Capt. Joseph Rosenfeld of Brooklyn, N. Y., has been decorated with the Croix de Guerre by the French for valor in the Kadish Sector while caring for the wounded.

Lieut. Walter J. O'Connel, M. C., U. S. Army, has received the Croix de Guerre for attending French wounded at Caen and Chateau Roux.

Deaths in the Service.—Lieut. George Washington Goins, M. C., U. S. Army, of Tooele, Utah, a graduate of Marion Sims College of Medicine, St. Louis, 1898, who was stationed at Jefferson Barracks, Mo., died at that place on March 14, aged 47 years.

Lieut. Lionel Andrius Anderson, M. C., U. S. Army, of St. Paul, a graduate of Washington University, St. Louis, in 1916, assigned to duty with the British Army Medical Corps, died from pneumonia, following influenza, at Namur, Belgium, on February 17, aged 31 years.

Capt. Robert Goldthwaite, M. C., U. S. Army, of Montgomery, Ala., a graduate of Bellevue Hospital Medical College, in 1893, on duty with the American Expeditionary Forces in France, died from meningococcus meningitis, in Base Hospital No. 26, Allery, France, on September 30, aged 46 years.

Lieut. Bennie Logan Englerth, M. C., U. S. Army, of Anna, Ohio, a graduate of the Eclectic Medical Institute, Cincinnati, Ohio, in 1915, aged 25 years, died from pneumonia while on duty with the American Expeditionary Forces in France, on December 16.

Lieut. Karl Cleveland Smith, M. C., U. S. Army, of Akron, Ohio, a graduate of the Ohio State University, Columbus, in 1911, on duty with the American Expeditionary Forces, died in France on February 27, aged 32 years.

Act. Asst Surg. William J. S. Stewart, U. S. P. H. S., a graduate of the University of Virginia, Charlottesville, in 1891, a surgeon in the Army Transport Service during the war with Spain, died in Caracas on March 11, aged 52 years.

Capt. Harold Montgomery Craig, M. C., U. S. Army, a graduate of the Detroit College of Medicine and Surgery, in 1911, died while on duty at Fort Stevens, Ore., from pneumonia, following influenza, on October 8, aged 30 years.

SOME LESSONS OF THE WAR.

IT would be a pity if beneath all the reek and welter of this worst of wars some slight benefit to humanity should not have been found, and indeed, speaking of medicine, we believe much good has already come out of it as some slight compensation for all the suffering and wretchedness. We are perhaps too near to it yet to be able to say what and how much we are to learn through the experiences of medical men in the war, but that something new, something valuable will be taught us we cannot doubt. Some day there will be published in Washington, in London, in Paris, and in Rome—perhaps even in Berlin and Vienna—ponderous tomes containing the medical history of the war as seen by the men of the medical corps of the several belligerent countries, and from them the student may dig out interesting facts and compare the experiences of many men and make useful deductions therefrom. But medicine cannot wait for these records, invaluable as they will be; what advantages are to accrue from the experiences of the war must be gathered from the literature of the present time, from the writings of those who tell what they saw and what they did while the facts are fresh in their minds, and perhaps, even before they are thoroughly digested—the digestion may be left in part to others to whom the facts are fed out.

It is with the object of collecting these facts that the MEDICAL RECORD has begun in this issue a series of papers from first hand sources, entitled "Medical and Surgical Lessons of the War." These papers will describe what has been done in the way of sanitation, medical organization, treatment of wounds and of disease, prophylaxis, discovery of new diseases, etc., noting especially the modifications in methods and procedures which experience has shown to be necessary—in short, the lessons which the war has taught us. The articles have been prepared by those who have had personal experience in the subjects of which they treat. They have been written by men in the Allied Armies as well as by Americans, the former being in many cases better qualified to speak authoritatively by the fact that they were in the war three years before us, and some of the lessons had been learned by them and applied before our own men appeared on the scene. In many cases, however, American surgeons struck out on fresh paths or effected notable improvements in technique and made new discoveries of great value. Such will also be fully described in this series of articles.

It will hardly be possible to present these articles in any orderly sequence, such as one would expect to find in a medical history of the war, but when the series is completed we shall have covered the entire ground of medical, surgical, and sanitary experiences, no lessons of importance and no facts of interest to the medical reader being omitted. The opening article, on page 639 of this issue, is by Colonel Nasmith of the Canadian forces who was among the first to offer himself in the struggle of right against might. Being among the first on the field he naturally could not rely upon the experiences of predecessors but had to strike out in many original lines for himself. His experiences, so far as they were of interest to the general public, have already been entertainingly told in his book, "On the Fringe of the Great Fight"; in the present article he deals with the practical details of sanitary work on the front. Col. Nasmith was a witness of the gas attack at Ypres and devised the first means of protection against it. He has also prepared an article on gassing which will appear in a later issue of this series.

LAPAROTOMY THROUGH THE AGES.

FOR many centuries, according to Durodié in the *Gazette hebdomadaire des sciences médicales de Bordeaux* for January 26, laparotomy was an operation limited to the castration of female animals for the purpose principally of fattening them, the sow being the one most in demand. The subject was well known to Aristotle and Galen. Female camels were also castrated to improve their powers for military uses; cows were sterilized for purposes not stated and bitches to increase their fleetness in coursing. There is a fable, or perhaps there was some truth in the legend, that ancient Lydian women were castrated as well as men for service as eunuchs. It was said to conserve their beauty, health and happiness. Similar rumors were in circulation concerning women in Egypt and Arabia. In comparatively recent times, accounts have been given of women in Hindustan who were castrated in childhood so they might grow up in possession of great strength and endurance and thus be useful as porters. If this account is true, and it seems well authenticated, the custom was doubtless very ancient and so may have obtained in the countries mentioned above. The author does not mention the sow gelder who was said to have castrated his lascivious daughter during the sixteenth century and who is usually referred to in histories of ovariotomy, but passes to the earliest writers on ovariotomy for cysts in the first quarter of the eighteenth century. The early articles were speculative only. Punctures of enor

mous cysts were made as early as 1710, and the number of punctures in individual cases went as high as 45. In 1746 Ledran substituted incision and this led in turn to extirpation, the first success being obtained by Laumonnier about thirty years later. Before his time there were several incomplete extirpations on record. Despite this and another success by Laugier the operation fell into disrepute until independently revived by MacDowell and others. In the early successes the cysts were probably small, but the growth removed by MacDowell was of such a size that its extirpation constituted an epoch in surgery.

But the history of laparotomy is something more than the history of ovariotomy, for, according to a contemporary document, during a mysterious epidemic in Paris in 1474, the belly of a living man was opened in the hope of saving his life; the symptoms were what would today be called "acute abdomen." It is said that the man recovered. This isolated episode is worthy of mention only as a curiosity of medical history, for it does not seem authenticated.

An account of laparotomy would not, of course, be complete without mention of cesarean section, but in antiquity this operation was performed only on the dead or dying and hardly belongs under surgical procedures. The first actual cases with intention of saving the mother and fortunate termination go back to the early part of the sixteenth century, one apparently in the year 1500. Before 1600 one woman is said to have been operated on successfully six times, dying under the seventh intervention. Paré knew of one success, but pronounced a favorable outcome almost a miracle. Nevertheless during the entire sixteenth century quite a few successes have since been placed on record. The operation did not encounter the violent opposition seen in most innovations, and the continuous success soon made it a recognized resource in obstetrics. Finally hints here and there, together with *a priori* reasoning, make it probable that abdominal section may have been occasionally carried out in antiquity under peculiar circumstances even if the fact escaped the treatises of the time. Otherwise a citation in Pliny is hard to understand. Two celebrated personages are said to have been subjected to an operation which could hardly have been cesarean section.

CLUBBED FINGERS IN CHILDHOOD.

THERE exists a type of clubbed fingers in childhood which differs from that met with in adults and to which the term of *acute* may very properly be applied. The digital hypertrophy undergoes its evolution at the same time as the affection upon which it depends and three quite distinct forms are met with in practice according to the nature of the affection giving rise to them. Hypertrophy of the ungual phalanx in tuberculosis develops very slowly, the extremity of the finger becoming broad and thick, but this process requires several years to attain a marked development so that the skin has time to keep in pace with the evolution and, therefore, does not become thin but remains normal. The nails widen but have not the same tendency to extend over onto the surrounding soft structures as in osteoarthropathy. Neither do they become thin as in the latter process, the hypertrophy is distinctly limited to the ungual phalanges and is painless. The process has no tendency to retrogression, on the contrary, it continues to increase. Congenital cyanosis is also slow in evolution; the fingers have the same drum-stick appearance as in tuberculosis but the greater rapidity in the development of the digital hypertrophy explains the thinness of the skin and nails frequently observed.

In osteoarthropathy, the hypertrophy also commences in the ungual phalanx, which hangs on the finger like an olive. The hypertrophied portion is separated from the second phalanx by a rather deep furrow. There is an enormous hypertrophy with thinness of the nails which tend to overlap the ungual margin and occasionally offer longitudinal striæ. The skin of the ungual phalanx is thin, smooth, rosy and transparent, looking as if it would burst from the distension resulting from the bone hypertrophy. At a more advanced phase of the affection the bone deformaties will be found extending upward on the limbs. . The lower ends of the two bones of the forearm become considerably hypertrophied, likewise the tibiotarsal joint. At the elbow and knee the bone changes are less evident but can be usually detected by careful palpation and always by radiography.

The ribs are sometimes slightly hypertrophied near the sternum, while the spine, in the dorsolumbar region, may be the seat of a kyphosis, a fact which distinguishes it from that arising in acromegalia which always takes place in the cervical region. Urticuria or eczema is met with over the diseased joints but pain is usually absent. It should also be remarked that clubbed fingers in childhood may likewise accompany pleural empyema of the chronic type, a clinical fact of considerable diagnostic value and which has not been sufficiently dwelt upon by writers on pediatrics.

PREVENTION OF MALARIA.

MALARIA is one of the diseases chiefly responsible for incapacitating the human machine physically, mentally, and economically. Wherever malaria is rife there the population is generally considerably subnormal. The war has crystallized attention on malaria, as a good deal of the fighting took place in lands notoriously malarious. The armies in Mesopotamia, Macedonia, and Palestine have at times been crippled by malaria, and, in fact, until preventive measures were brought into full sway, military offensives had to be delayed.

During 1917 one hundred and seventy-eight cases of locally acquired malaria were recorded in England. The areas affected were mostly those in which ague had been very prevalent up to the middle of the last century, and it is probable that in

these and other areas a considerable risk arises of the reestablishment of endemic centers of malaria owing to the return from abroad of men who are carriers of the parasite of malaria. It may be recalled that until the marshes in the eastern counties of England had been drained malaria was quite frequent in that part of the kingdom.

In this country the problem is different, and, as is stated in Public Health Reports, March 21, 1919, the public generally has no conception of the seriousness of malaria as a health problem. Seeing that competent authorities estimate the number of cases of malaria occurring annually in the United States at about six or seven million, the influence of this disease on the health and welfare of the nation certainly demands wider recognition. As for the South, there need be little hesitation in saying that typhoid fever, dysentery, pellagra, and tuberculosis all together are not as perniciously important as malaria.

Theoretically, the control of malaria is comparatively easy, as the control of malaria is bound up with the destruction and control of the anopheles mosquito. It is known with scientific exactitude how to destroy and control this species. But the financial aspect of the situation must be considered. Malaria is seven times more prevalent in rural communities than in urban districts, and the country sections, as a rule, have only limited resources with which to fight the enemy. A feature of malarial infection of the utmost consequence is that it is most injurious to children; it affects them when they are growing and tends permanently to sap their vitality. A great deal of the laziness which is inherent in the poorer classes of the swampy Southern lands is constitutional and induced by malarial infection. The malarial problem is also as important economically as it is hygienically, for one involves the other. A man or woman with so devitalizing an infection as malaria cannot work properly, and therefore a district in which malaria is present is an economic loss to the nation.

PSEUDOINFLUENZA.

It is hardly necessary to emphasize the necessity of keeping separate the two affections, pandemic influenza and false influenza. The latter usually means endemic grippe, winter catarrhal fever, etc. The former is enormously diffusible and spreads from man to man and country to country with great rapidity, and occurs without reference to season of year. The latter occurs only in the winter months and is never imported, but develops autochthonously, but may show epidemic qualities in institutions and barracks. Before the recent pandemic true influenza was ascribed to Pfeiffer's bacillus, while the false form could be due to any one of several ordinary pathogenic organisms, notably the pneumococcus and streptococcus. At the present time the exact causation of true influenza is unknown. A striking difference between the two types is seen in the development of acquired immunity, for in true influenza such immunity may result from a previous attack, even of remote date, but in false influenza relapses occur with each winter. A problem for future discussion will be the relationship between false influenza and tuberculosis, for annual recurrent winter grippe often carries with it a suspicion of latent tuberculosis.

But the term spurious influenza is associated with other conditions still, and in last summer's pandemic in Europe it became apparent that there were spurious cases which were in no sense grippal. Keyser relates a number of these in the *Norsk Magazin for Laegevidenskaben* for January. This affection appears to have been isolated for the first time in Germany, where it passed for months as malaria. The cases in reality long antedated the pandemic and were evidently first seen in the summer of 1917. Keyser himself had treated over 300 cases since June 17, 1918, most of them occurring side by side with pandemic influenza. In the Norwegian cases no typical eruptions appeared. The resemblance to influenza was so marked that the diagnosis must have been difficult. Rare complications were seen. In one patient with conjunctivitis and angina and severe pains a lumbosacral herpes zoster broke out, while in another a critical rash of urticaria appeared. A third patient presented a general lymphadenopathy and a fourth tuberculous epididymitis, both with catarrhal fever. Two other patients had mild croupous pneumonia. Isolated conjunctivitis was seen fifteen times. These cases, or at least those seen after the pandemic appeared, were at first set down as "Spanish" influenza, and it is by no means apparent how the author succeeded in excluding the latter, for he says nothing of differential diagnosis. Apparently he bases his opinion on the similarity of the cases to pseudoinfluenza as visualized by the German authors.

A Unified Health Service.

If experience has taught mankind anything, it has taught with most convincing clearness that good sanitary and hygienic conditions are essential to the maintenance of health, and that by the expenditure of brains, energy, and money, such conditions can be established. But it must be borne in mind that in order to obtain the best results in any human endeavor cooperation and organization are necessary, and consequently to bring about nation-wide good results in health affairs the same rules must be applied to federal problems as were applied during construction of the Panama Canal and in the camps in Europe and this country during the war. In Public Health Reports of February 28, 1919, is published a paper by Assistant Surgeon General B. S. Warren on a Unified Health Service, in which the writer points out that the Federal Government has at least three definite responsibilities in the field of public health, namely, international control of disease, interstate control of disease, and a general interest in the health of all the people from the general welfare point of view. It is shown that Federal, State, and local health authorities in some degree have identical responsibilities, and that for these reasons, if we are to have a "unified health service," there should be very close cooperation on

account of the community of interest. With regard to the question of cost, it is pointed out that at the present time the people in the United States are paying out money sufficient for the maintenance of an adequate medical service, but fail to receive it. The money is spent in such a haphazard manner that the service is not only often inadequate or worthless, but at times actually harmful. For drugs alone the United States spends $500,000,000 a year. This sum, if properly expended, would buy all necessary drugs and leave a balance sufficient to add $2,000 a year to the income of each of the 125,000 physicians in active practice in the country. In short, with a proper organization, distribution, and training of the medical and sanitary personnel of the country, and a proper expenditure of the funds now being spent for medical purposes, there would be available for every needy person adequate medical and hospital services and supplies. With such service closely coordinated with or forming part of the health department, it needs no argument to show that disease prevention would begin at the source. A list of recommendations compiled from reports made by Surgeon Carroll Fox of the U. S. Public Health Service, which, in the opinion of the writer, should form the basic principle upon which to build a State health department, is given; however, the main point insisted upon is that a health department, whether urban or rural, and whether organized on part time or on all time service basis, should be correlated with the State Health Department, so that a unified health service would be the result.

News of the Week.

Grip Epidemic at Sidney.—According to a special cablegram received in Vancouver on April 8, hundreds of new cases of influenza are reported at Sidney, N. S. W. The Government has closed schools, theaters and motion picture houses and prohibited other public gatherings.

Grenfell Association Asks Help for Labrador.—The Grenfell Association has received a letter from Dr. Wilfred T. Grenfell, medical missionary to Labrador and northern Newfoundland, telling of the ravages of the recent epidemic of influenza in that country. In the Sandwich Bay region according to this communication 20 per cent. of the population perished, and similar numbers died in other localities. The letter emphasizes the need of additional buildings for the Brick Orphanage maintained by the Grenfel Association in order to care for the children whose fathers and mothers died during the epidemic.

Addition to Memphis Hospital.—The Trustees of the Baptist Memorial Hospital, Memphis, Tenn., plan to erect an addition to the present building at a cost of approximately $250,000. After its completion this hospital will be one of the most complete in that section of the country. The plans also include provision for a nurse's training school.

Foundling Hospital in Need of Funds.—A campaign was opened on April 7 by the advisory committee of the New York Foundling Hospital to raise $250,000 with which to pay off the debts of the institution and give it a fresh start in the care of foundling children. During the fifty years of its existence the institution has cared for more than 70,000 foundlings, and has under its supervision at the present time more than 5,000 children.

Medical Conference at Cannes.—A conference of medical experts is in progress in Cannes, France, in preparation for the convention of the Red Cross Societies of the World. The subject under discussion during the week of April 7 was a specific program for a plan to establish an international bureau of health, where the latest scientific discoveries may be collected and the means of their application discussed. Dr. Hermann M. Biggs, who has been given a six-weeks' leave of absence from his duties as Health Commissioner of the State of New York in order to attend the conference, presided at the opening session.

Conference of Baby Welfare Workers.—The sixth annual conference of the Babies' Welfare Association of New York City was held at the Russell Sage Foundation on April 8, under the chairmanship of Dr. Henry Dwight Chapin. Dr. S. Josephine Baker was the principal speaker.

New York Health Department Plans Baby Show.—It is announced that the New York City Health Department will conduct a children's department in connection with the Milk Exposition to be held in the 71st Street Armory during the week of April 21. Elimination baby contests will be held in the five boroughs and a final contest will then be conducted at the Milk Exposition. The Health Department is using this as an opportunity of impressing on parents the food value of milk.

Clinic for Drug Addicts.—The New York City Health Department recently opened a clinic in the Health Department Building, 139 Center Street, where it is supplying drug addicts who come to it with prescriptions enabling them to obtain at cost the small dose of the drug to which they have become accustomed and which is necessary to prevent them from becoming seriously ill. The plan is to encourage drug users to obtain their drug in this way in order to help break up the trade in narcotic drugs which has grown to such alarming proportion during the past few years. About 75 addicts availed themselves of the clinic the first day it was opened and the number ran up to 200 and over on subsequent days of the week. It then became evident that larger quarters would be needed and the clinic was moved to 145 Worth Street, and will be kept open evenings. Here, 132 addicts applied for narcotics within ninety minutes after the doors were opened. Several conferences have been called to consider ways and means of controlling the drug evil which were attended by Federal, State and city authorities, and representatives of the county medical societies of the five boroughs of the Greater City. At one of these conferences Senator Whitney reported that within the last month certain physicians, whom he named, had made application for 160,000 drug prescription blanks. Other figures were submitted showing that three physicians within the last six months had issued 1,500,000 prescriptions. The sale of drugs at price is the means which the Health Department relies on to offset this traffic in narcotic drugs by doctors and druggists. Internal revenue officers have been rounding up physicians and druggists, a number of

whom have been arrested and held in bail for various sums ranging from $2,000 to $5,000. The Physicians Protective Association has passed resolutions against these raids. The resolutions declare that the clause in the Federal drug act which requires the physician to reduce each day that quantity of a drug administered to a patient is based on a fallacy, and uphold the right of the physician to prescribe for the drug habit as for other diseases.

Mr. Walter R. Herrick has been appointed Commissioner of the Department of Narcotic Drug Control of New York State.

Typhus Fever Spreads in East.—Reports received at the Red Cross Conference at Cannes, France, from representatives of the Red Cross in Eastern Poland, Russia, Serbia, and Macedonia announce the progress of typhus fever in these countries to an extent that is extremely serious. A committee of experts was appointed at the conference to advise the organization as to means for combating the spread of the disease so as to prevent its introduction into Italy, France, and England.

Red Cross Work in Greece.—The American Red Cross is now maintaining a commission in Greece which is cooperating with the Greek Government and rapidly extending its activities. The commission spent $68,860 in Greece up to January 21 last and estimates that it will need $1,305,000 to carry on the work planned for the first six months of this year.

United States Training Corps for Women.—During the war the various governmental departments at Washington, recognizing the need of some system of physical training which would keep women employees in fit physical condition, organized under the direction of Miss Susanna Cocroft the United States Training Corps for Women. Military drill and setting up exercises were adapted to the needs of the women and several thousand Government employees joined the corps. The results of this training were so marked that they suggested a profound need for recreational camps where health giving instruction and entertainment could be given to women who need conditioning, and to meet this need it is planned to make the organization national in scope. These plans provide for the establishment of large recreational camps for women to be located in the west, in the north central States, in the south, and in the east. These cantonments are to be under proper medical and nursing supervision. They will be open to all women who need a wholesome, constructive vacation. The activities of these camps will include ordinary setting up exercises, drill in the school of the soldier, directions in deep breathing, correct posture, and wholesome recreation. Recreational camps will be arranged outside of large industrial centers where women employees may live during the summer and go back and forth to their work. Plans are also being developed to extend the plan so that a semi-military drill may be given to all children in our public schools. The work of the United States Training Corps for Women is to be supported by voluntary contributions.

Lieut.-Col. Stuart McGuire has been elected president of the Medical College of Virginia, and will assume his new duties at once.

Harvey Society Lecture.—The seventh and last of the present course of Harvey Society lectures was delivered at the New York Academy of Medicine on April 12, at 8.30 P. M., by Dr. Stewart Paton. The subject of the lecture is "Human Behavior in Peace and War."

Law to Limit Medical Fees.—It is reported that a measure has been introduced into the Missouri Legislature prohibiting medical men from charging a fee of more than $10 for any treatment, and imposing a fine of $10 to $100 for violations.

Traffic Accidents.—The toll of traffic accidents in New York City for the month of March was 53 persons killed by automobiles, nine by trolleys, and two by wagons, according to the report of the National Highways Protective Association. In New Jersey 14 were killed by automobiles and four by surface cars. For the first three months of the year 192 persons have been killed by motor cars in New York State, 21 by trolleys, and 12 by wagons.

New York Neurological Society.—The next regular meeting of the New York Neurological Society will be held at the New York Academy of Medicine, on May 6, 1919, at 8.30 p. m.

The Medical Association of the Greater City of New York.—The twentieth anniversary meeting of the association will be held in Hosack Hall, New York Academy of Medicine, 17 West Forty-third Street, Manhattan, on Monday, April 21, 1919, at 8.30 P. M. A paper will be read by Major Charles A. Mix of Chicago on "Neurocirculatory Asthenia," and one by Dr. John B. Deaver of Philadelphia, on "The Possibilities of Gallstone Pathology."

Gifts and Bequests.—The will of Emil Schweinburg of New York, provides for the following bequests: German (Lenox Hill) Hospital and Dispensary, Home for Aged and Infirm Hebrews, Montefiore Home for Chronic Diseases, Charity Organization of New York, and National Jewish Hospital for Consumptives, Denver, each $2,500; Lebanon Hospital, St. Marks Hospital, Hospital for Deformitives and Joint Diseases, and Mount Sinai Hospital Training School for Nurses, each $1,000; United Hebrew Charities, $5,000.

The Late Dr. Emmet.—At a recent meeting of the Surgical Board of the Woman's Hospital of New York, the following preamble and resolutions were adopted:

Dr. Thomas Addis Emmet died on March 1, 1919, in New York City. His career was so closely linked to the history of the Woman's Hospital in the State of New York that we, the Surgical Board, deem it proper and fitting to register our sense of loss and regret. Dr. Emmet was born at Charlotteville, Va., on May 29, 1828. His father was at that time a member of the faculty of the University of Virginia, having been appointed to the position by Thomas Jefferson. He was appointed in 1856 assistant to Dr. J. Marion Sims in the recently founded Woman's Hospital, and was surgeon from 1862 to 1900. During this period he developed the methods and enunciated the teachings that made him known to the entire medical world. Resigning from the hospital and active practice in 1900, he passed the last years of his life surrounded by his beloved books and documents, and living in dignified and respected retirement. As a writer and author of many textbooks and articles he became widely known. His works were translated into several languages, and brought many to study and learn his methods, for it

as recognized that only by seeing him at work could ie detail of his methods be thoroughly comprehended. was thus he preferred to teach. As a surgeon he ood pre-eminent, and, in the opinion of many, his astic work has never been equalled. Those of us, nong the older alumni of the hospital, who have orked and served under him, cannot fail to remember ith a deep sense of gratitude the training he gave. ı our anxieties and troubles there was none to whom e turned for advice and council as readily as to him. ountless instances of his kindness to the younger ırgeons might be told, and his invitations to meet ıe prominent physicians of the day at his home and his table won for him in our hearts and minds a ace that will never be forgotten.

Whereas, We who have followed him in the service the hospital as its medical officers, now learn of his ath, be it

Resolved, That we officially recognize our deep sense regret and sorrow, together with our profound spect, admiration and love for his memory. Be it rther

Resolved, That a copy of these resolutions be sent his family, and to the medical journals.

T. H. L. McGINNIS.
LEROY BROUN,
Committee.

Obituary Notes.—Dr. EDWARD M. HYLAND of tica, N. Y., died after a prolonged illness, on pril 11, aged 60 years. He was a graduate of ellevue Hospital Medical College, in 1883, and ırgeon in charge of St. Elizabeths and St. Jo-ph's Hospital and Home of Utica.

Dr. GALUSHA BURCHARD BALCH of Yonkers, a raduate of the College of Physicians and Sur-ons, in 1860, died at his farm in Richmond, Mass., April 8, aged 80 years.

Dr. CYRUS HENRY PENDLETON, at the time of his ath the oldest active physician in the State of onnecticut, died at his home in Hebron, Conn., re-ntly, at the age of 89 years. He was a descendant Mayor Bryan Pendleton, who came to America in 30, as the first Governor of Maine. Dr. Pendle-n was a graduate of the Western Reserve Univer-ty Medical Department, Ohio, in 1860, held many tate and county offices, and was presidential elector the Cleveland ticket in 1892.

Dr. JEFFERSON SCALES of New Brighton, Staten land, N. Y., a graduate of Jefferson Medical Col-ge, in 1867, died on April 14, aged 71 years. He ught in the Confederate Army during the Civil ar, was former president of the Richmond County edical Society, and a member of the Medical Asso-ation of the Greater City of New York. He was nsulting physician to the S. R. Smith Infirmary, t. Vincent's and the Sea View Hospitals.

Dr. FRANK FINNEY, a graduate of Bellevue Hos-ital Medical College, in 1885, died at his home in a Junta, Col., on March 23, aged 61 years. He was hief surgeon of the Santa Fe Hospital and largely nterested in financial affairs in Colorado.

Dr. EDWARD STILES ALLEN, a graduate of Belle-ue Hospital Medical College in 1876, died suddenly heart disease at his home in Providence, R. I., n March 28, aged 63 years.

Dr. JAMES A. HUTCHESON, a graduate of the Long sland College Hospital, died at his home in Lyn-rook, L. I., from complications following an attack f influenza, on March 30, aged 62 years. He served or some years as health officer of the town of Hemp-tead.

Dr. PAUL H. TRACY, a ship surgeon, 53 years of ge, died suddenly in New York City on March 28.

Correspondence.

POSSIBLE BENEFITS OF RESPIRATORY NARCOSIS IN PREVENTING INFLUENZAL PNEUMONIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Notwithstanding the natural medical antipathy to advocating anything new in the way of treatment that is not backed by accepted theory, I venture to offer a suggestion in view of the widespread acknowledged helplessness in preventing pneumonia complicating influenza.

I studied medicine because of an inherited tendency to many repetitions of attacks of bronchitis. I probably have had at least two attacks a year ever since I can remember, many of which have been of influenzal origin; and innumerable threatening congestions. When I was a very young man, the late Professor Loomis wrote me a prescription containing opium and Hoffman's anodyne. In the course of years I have modified the excipient with an apparent energizing influence in the sum-total effects secured. I have never had my pharmacist make up the prescription given below, preferring to produce the effect of my own compounding. I have all the constituents made for me separately, and I do the compounding. It requires a period of holding and blending to secure the best result. There is no question that my life has been prolonged by this medicine.

The most attractive theory I have read as to the causation of pneumonia complicating influenza is that the intensity of action in the larger air passages and the character and amount of the mucoid product act, through gravitation downward, to clog the air cells, and hence incite the pneumonic process. If this is so, why not do as I personally have done hundreds of times to myself, and secure sufficient sedation of the respiratory tract to moderate at least the intensity of the morbid action, and frequently entirely stop it? It seems probable that the same influence which relieves pain and discomfort also depresses vital activity in the invading bacteria, as well as in the cells of the mucosa. Hoffman's anodyne of the best makes is soothing, and is nearly all exhaled through the respiratory structures. In some cases it is the only agent that will go directly to and favorably affect the smaller air passages. In my bad attacks I also use active counterirritation. Camphorated oil on the nose externally is the best "cold in the head" remedy that can be used. Mustard pushed to even a blistering effect, applied at various areas of the chest, is vastly helpful. Breathing cool air, but not so cold as to be irritating, is also helpful. Usually if enough of the sedative is given, circulatory activity is sufficiently repressed, without requiring rest in bed. The late Dr. Alonzo Clark used to commend to the consideration of his classes the maxim that "God shall be feared and the intestinal tract be kept patent." He also used opium for peritonitis with beneficial results.

I submit the suggestion for what it may be worth. Light attacks may not kill when severe ones would. It may be worth trying somewhat extensively. The prescription follows:

℞	Grams
Tinct. opii	4
Spts. ætheris comp	17
Glycerini	32
Syr. pruni virg	32
Syr. tolutani	21
Syr. picis	10
Syr. glycyrizæ	10

M. Sig.: Teaspoonful every three or four hours.

This formula costs too much to permit its being used as an advertised nostrum; but if some manufacturing pharmacist could hit the knack of compounding it so as to secure the right effect, it could be dispensed under medical direction. After all, the profession will ultimately be called on to direct the consumption of all narcotics and stimulants.

J. M. W. KITCHEN, M.D.

EAST ORANGE, N. J.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, March 20, 1919.

An Important Amendment to the Ministry of Health Bill by the Standing Committee.—The Standing Committee of the House of Commons which is now considering the clauses of the Ministry of Health Bill, have adopted an important amendment without discussion and in the face of protests from Dr. Addison, the President of the Local Government Board, and Mr. H. A. L. Fisher, the President of the Board of Education, these being the two cabinet ministers whose departments are immediately concerned. The bill, it will be remembered, proposes to combine under one State Department the existing responsibilities of the Local Government Board so far as health is concerned, and all the functions of the National Insurance Commissions for England and Wales, and also to include the duties of the Board of Education in respect of the health of expectant and nursing mothers and children under five years of age. With regard to the medical inspection or treatment of children of school age and young persons, which now appertains to the Board of Education, on the introduction of the bill it was understood that that board would not resign without real regret its functions in these directions, and it was believed that no such step would be found immediately necessary. Mr. Locker Lampson, however, proposed an amendment to provide that *all* the powers and duties of the Board of Education with respect to the medical inspection and treatment of children and young persons should be transferred immediately to the new Ministry of Health. The amendment was put and carried without a division and in deference to the clear feeling that the committee was strongly in its favor. In the view of the committee, as the object of the bill was to take over the health services from the various departments of the State, with the intention to prevent overlapping, medical inspection and treatment of school children should not be left outside the scope of the bill. Dr. Addison pointed out that under the bill there were two categories of services; first, those to be transferred forthwith, and secondly, those for whose transference opportunity would be made later on; and it is fair to him to point out that, while the bill provided for the immediate combination of certain existing activities, it also proposed to give the new Ministry power to bring within its scope other considerable health duties to be directed under intelligent guidance toward the maintenance of the national health on higher planes. But to leave the medical inspection out of the first category was an error in tactics. It was felt by many medical men at the time of the first reading of the bill four months ago, that the medical inspection of school children and young persons was an important part of the duties of any Ministry of Health, and that there would be a protest against this omission from the immediate scope of the bill. When the bill was drafted there is no doubt that those in charge of the task found that to attempt to concentrate within one act the general administration of all things relating to the health of the nation was beyond their ingenuity. With such a gigantic charge any administrative machine would run a great chance of breaking down. While medical men welcome the amendment as taking in the present a most important step which it was intended to take in the early future, it is impossible not to see the force of Dr. Addison's protest that if every responsibility indicated in the two categories were to be thrown upon the Ministry of Health at once, failure might follow. The amendment will probably be considered on the report stage from this point of view, but the probability is that the strongly expressed opinion of the Standing Committee will have its outcome in legislation. It will be very unfair if the amendment seems in any way to cast a reflection upon the admirable work done in the inspection and treatment of school children by the medical officers of the Board of Education. Their energies have been most wisely and sympathetically employed, and have been rewarded by much improvement in many of the children attacked. There seems, however, no reason why similar success should not follow similar tactics when employed under a Ministry of Health.

The Demobilization of Medical Men is at last proceeding apace, and the scandal of keeping some 9,000 doctors with the colors when the home community is starved for want of medical service is abating. And with the doctors nurses are also returning home.

An Experiment in Hospital Administration.—A few days ago the authorities of the London Hospital, the largest voluntary hospital in the metropolis, decided to fill the vacancies on the honorary medical staff of the institution created by the retirement of Dr. Frederick J. Smith and Dr. Henry Head, by the appointment of whole-time paid medical officers, consisting in each case of a director, three clinical assistants, and a laboratory and clerical staff. This of course is a tremendous revolution in connection with the English system of voluntary hospitals, under which the duties of the medical staff are and have been always rendered gratuitously, the reward for their services being supposed to emerge indirectly from the following two things: first, the

unrivalled clinical experience must elevate them in the eyes of the public to the position of distinguished medical men; and, secondly, in their rôle of consultant they would be supported by their pupils from the medical school affiliated to their hospital. No one can say that so simple a plan of obtaining the best medical service for a charity at no expense to the charity has not much to commend it; as a matter of fact it has so much to be said in its favor that it may be a long time before the example given by the London Hospital is followed by any other large metropolitan hospitals having schools attached. On the other hand there is no doubt that the cause of medical education may be found to be better served under the new plan. It must be remembered that the medical school of the British pattern was not invented as a whole but is the result of reconstruction, time, change of public thought and public standards of education, and a crowd of other circumstances. At the present moment, as has been lately said in these letters, medical education has become a very expensive affair in this country. Students concerned in the instruction for a medical career are not drawn from the wealthy class by any means, and are often hard set to find the necessary fees and living expenses of a curriculum extended nominally over five years and really over six. There is extraordinarily little margin left with these lads to pay their teachers, and in the meantime the work of teaching, given cheerfully by the medical staff when it was infinitely briefer and to some extent paid, is now very onerous, with the risk that many of those to whom it falls to deliver the lectures and organize the demonstrations are by temperament unfitted to discharge the task. Moreover many of them can ill afford the time in which to carry on the systematic work of medical education if much of their day is already occupied by their purely clinical and unpaid services. It is true, as I have said, that these services are supposed indirectly to command a professional income outside the walls of the hospital, but it is not much good to a physician or surgeon to say that he can take unlimited patients in private practice, if he has no leisure to see such patients in either his consulting room or house. Again medical education has become a highly specialized affair, particularly as regards the preliminary scientific training. It may be no trouble, and on the contrary it may be a very useful pleasure, to a young physician, a young surgeon to review for a discriminating class of his juniors the cause, treatment, diagnosis, incidence, and so on of a disease with which he is in professional touch. That is bringing the theory and practice of medicine together in the most valuable manner for teacher and taught. But it is a totally different thing if the same young practitioner is asked to lecture on the biology and physics which underlie his rational attitude toward his patients. To ask such a man to keep in touch with the developments of pure science when his daily work is to keep track of pathological variations from these scientific phenomena is to ask too much. When anatomy meant osteology, and not comparative morphology; when physiology meant the mechanism of cardiac motion and respiration with no regard to general biology, and when physics meant the mechanism of the common pump, the ancillary sciences could be imparted by any clear headed young man three years ahead in his studies of the classes which he was addressing. But to-day the teaching rôle becomes at the same time a sacrifice on the part of the honorary staff, possibly a distasteful occupation, and certainly one for which proper emolument should be forthcoming. The move of the London Hospital is therefore progressive; it is toward the institution of a medical staff whose duties, while ministering to their patients, would also be to instruct the students on scientific lines, fitting them for future research work. But it is not easy to see where adequate salaries can be found to recompense such whole-time officers unless the public comes to the rescue. Medical education cannot be paid for out of money given directly for the needs of patients. The action of the London Hospital must, therefore, be regarded as an experiment, but it is a particularly valuable one, as shaping the education of medical students upon a university pattern. The metropolitan medical schools are already integral institutions in the University of London. These new medical officers will really be university teachers of medicine along lines analogous to those pursued in other faculties. The medical officer directing medical studies will be in intimate touch with the purely scientific education of his students, with their clinical training in the wards, and with their further work in the laboratories. A medical school conducted on those lines would be a proper part of the university faculty, and those interested in medical education will view this experiment with anxious attention.

The Medical Parliamentary Committee.—This committee has been steadily at work drawing up a scheme which it is proposed to submit at an early date for the opinion of the medical profession. The purpose of the scheme is to institute some central body representative of all classes of medical opinion which shall hold a watching brief, in the interest of the public, over all legislation of a medical nature. The interests of the medical profession, it is obvious, are bound up in a good administration of medical service from the public point of view.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, March 7, 1919.

Sanitary Aviation on the Edge of the Sahara.—Professor Tuffier, having been called to see a general who had been seriously wounded at Tafilet, an oasis on the border of the Great Sahara, by a shell splinter, which passed through the lower end of the sternum and lodged behind the heart, points out how aviation may be made serviceable in the desert to both physicians and patients. This officer had been wounded at a distance of 945 kilometers from Oran, 275 kilometers (172 miles) from a railroad, equivalent to a nine-days' march, and had been carried back a distance of 25 kilometers on a stretcher. Two surgeons were dispatched per air-

ship. One, starting from Fez (300 kilometers, or 187 miles) reached the patient in three hours and ten minutes, after passing across the mountains at a height of 4,000 meters. This is the minimum time required for wounded soldiers to reach a field hospital at the front. The surgeon coming from Bou-Denib (100 kilometers, or 62½ miles) arrived at the same time. As the aid post of Ksar-Es-Souk was altogether too primitive, buried in the desert without any instrumental outfit, while the patient's condition was a serious one, he was transported in an ordinary fighting aeroplane to Bou-Denib, accompanied by the two surgeons. There the position of the projectile and the condition of the lung could be ascertained by means of radiography; and Tuffier was enabled to apply the necessary treatment. He found the patient in very bad shape, with a large, bloody extravasation behind the heart and the root of the lung. An operation was performed, and for the time being all danger was averted. Later the patient was operated upon for pleural empyema.

Availing himself of this opportunity, Tuffier investigated the conditions of evacuation of the wounded during the engagements on the Sahara positions. An experiment made with the aeroplane of Dr. Chassaing, the first to carry out sanitary aviation, showed that soldiers with the most serious wounds (fractures of the thigh, fractures of the arm) could be easily transported a distance of 65 kilometers in three-quarters of an hour, after a flight over the insurgent regions. The wounded arrived in excellent condition, without having been subjected to any suffering. Of 60 wounded in September, 1918, 15 had already been carried by aeroplane, in less than an hour and ten minutes, a distance of 110 kilometers (65 miles).

In the South Algerian posts, an aeroplane route has been organized which insures the evacuation of the wounded and the transportation of surgeons. It extends as far as the Sahara center of In-Salah, more than 370 kilometers from all railroad connections. Camel or mule convoys require 26 days to carry the wounded from In-Salah to Ouargla; the best available routes permit no shorter journey than seven days. French air pilots traverse this distance in two relays, either the same day, or on two successive days, in about seven hours. The same organization exists in southern Tunis.

The advantages of aeroplanes for the evacuation of the wounded consists not only in this economy of time, but in the possibility of penetrating into posts which are practically all invested. In Morocco, of 37 Sahara posts, 14 are completely blockaded, and can be supplied with rations only two or three times yearly. The same is true regarding troops on the march; the wounded must follow the column on stretchers, as otherwise they would be killed by the enemy, who closes the way behind the marching troops.

For this evacuation, special improved sanitary aeroplanes should be provided, opening on the side; these are needed for cases of severe wounds of the head, chest, and abdomen. However, the number of such planes may be limited, since any observation or bombing aeroplane can transport men with slight or moderately severe wounds in the place of the observer. This plan was followed in many cases.

A fixed and determined air route, with landing stations every 200 kilometers, guarantees perfect security.

The only obstacles to aviation in the Sahara Desert are the temperature and the resulting atmospheric disturbances, which force the pilots to remain at an altitude of 1,500 or 2,000 meters during the summer time. The most serious enemy of sanitary aviation, however, is the sirocco, with its dust clouds, which render landing so dangerous that the air route remains closed for about one out of every four days during the heated term.

In spite of these drawbacks, sanitary aviation is an accomplished fact, and recourse to it will become more general for the relief of civilians and natives as well as for the troops. Undoubtedly it will provide a means of penetration and pacification of insurgent territories.

Le Fort's Work in Surgery of the Heart.—In the last three years, Prof. René Le Fort of Lille has published a considerable number of papers on the surgery of the heart and mediastinum. In 1916 he advocated in a paper read before the Paris Academy of Medicine the extraction of foreign bodies from the posterior or anterior mediastinum through a wide anterior transpleural route, reporting the results in his practice of 12 cures in 12 cases. The opening of the pleura to reach the mediastinum was a new idea, which was accepted without objection by the majority of operators. In his later articles Le Fort points out the slight gravity of surgical pneumothorax, which is readily tolerated by patients whose myocardium is not seriously affected, and the advantages of primary wide and complete opening of the pleura. This is not to be dreaded; it relieves the respiration, and its performance serves to make thoracotomy as easy and quick an operation as laparotomy.

Le Fort endeavored to formulate the rules for these operations. He carried out a thorough radiological investigation of projectiles in the mediastinum and of the physiological movements in the mediastinum, and especially in the heart. His findings, which are often contrary to the accepted views have been published in the communications to the Academy of Medicine and in various contributions to medical periodicals. In a book published in 1918 on projectiles in the mediastinum, and in an article in the *Revue de Chirurgie* for 1917, the author discusses at length the pathological anatomy, symptomatology, diagnosis, course, prognosis, and treatment of foreign bodies in the mediastinum.

He is opposed to all operations which permanently mutilate the thorax. Resections of cartilages or of portions of ribs should always be avoided, in his opinion, the remote results yielded by those procedures being uncertain and often unsatisfactory. While very discriminating in his choice of procedures, and accepting for certain special cases the transsternal route, and even exceptionally the posterior route, the author advocates for all really complicated and difficult cases the wide anterior route and in particular the large flap with external hinge of Delorme, which he has improved upon. This route provides the most space. Among new procedures recommended by Le Fort must be mentioned in the first place simple incision of an intercostal space combined with division of one or several

costal cartilages, above or below the line of incision. This procedure gives free access to the lower portion of the mediastinum and to the hilus of the lung. For the region of the cervicomediastinal "crossroads" Le Fort has devised the sternocleido-costal flap, which permits the temporary turning outward of the clavicle and the first rib, with the corresponding sternal segment, without dividing the clavicle or the first rib, and without opening the sternoclavicular or costal articulations.

With the assistance of these various methods, Le Fort, at the time of the present writing, had performed over 100 extractions of projectiles from the mediastinum or its immediate vicinity. Eleven bullets or shell splinters have been removed from the walls or the cavities of the heart, and so far as we know he appears to be the only operator who has extracted projectiles from the wall of the left auricle and from the cavity of the left ventricle. A large number of his operations were upon wounded soldiers who had been repeatedly advised against surgical intervention, and who passed from one service to another looking for a surgeon willing to operate. Many others had probably undergone one or more unsuccessful attempts at extraction; of these men, many were sent to the author, in conformity with his request, by colleagues who kindly entrusted him with their bad cases. The results continued to improve in the course of years. In 1916 and 1917, 82.3 per cent. of the projectiles sought for were extracted; in 1918 and the beginning of 1919, 100 per cent. of the projectiles sought for were extracted. In 1916 and 1917 the post-operative mortality was 8.7 per cent.; in 1918 and 1919 it was nil. These improved results are due to the more and more complete abandonment of narrow routes of access, but especially to the choice of the posterior route and investigation of improved technical methods.

I. Alkali Treatment Applied to the Acidosis of Epidemic Influenza.—Thomas C. Ely is of opinion that the chief cause of death in the influenza epidemic has been the overwhelming acidosis. He points out that it is an established fact that acidosis is a constant factor in all infectious fevers. As a clinical sign in the recent epidemic he cites the peculiar acetone odor of the breath which was so characteristic that in some cases a tentative diagnosis was made on this alone. His treatment has been to combat the chief cause of death and prevent the acidosis by administering the essential alkalies, and in his practice he has had only one death that could be attributed directly to the influenza. Three other fatal cases he attributes to preexisting conditions. The method of treatment followed was: Immediate elimination by means of profuse sweating induced by large bowls of hot boneset tea, and divided doses of calomel, one-tenth grain every half hour until a grain or more had been given. Water was given exclusively for the first twenty-four or forty-eight hours, and freely throughout the attack. Hot mustard foot baths were used, the patient being kept in bed covered with blankets and surrounded with hot water bottles. A teaspoonful of sodium bicarbonate to a pint of lukewarm water was given every four hours by enema. The alkalies were given as follows: sodium bicarbonate one-half ounce, peppermint water four ounces, teaspoonful every two hours, alternating with the same dose of potassium citrate one-half ounce, peppermint water four ounces. Calcium salts were given in the form of lime water one-third, milk two-thirds. In some cases the potassium salts could not be tolerated. The usual cardiac and respiratory stimulants were also administered; oil of terebinth was found of use, particularly after crises. The author states that physiology, pathology, and physiological chemistry all show that acid poisons if not neutralized become dangerous and often fatal and that in high states of toxemia the body bases are soon used up. By the treatment indicated the body bases are supplied from without and remedies are avoided which contain an element of danger, such as opium, atropine and belladonna which check secretions and lock up poisons which should be eliminated. To the contention that the chief cause of death has been pneumonia, Ely replies that the fatal lung condition might not have developed had the body bases not been exhausted in Nature's effort to combat acidosis, and that the same acidosis may explain death by nephritis. Moreover, the claim that death was due to cardiac involvement may be answered by the statement that the heart might have been better equal to its task if the body bases had remained in normal condition. Finally, the use of alkalies is founded on the laws of Nature and should prove of value not only in the profound toxemia of epidemic influenza but in other severe infectious diseases and in all critical toxic conditions.

8. Epidemics After Wars.—George A. Soper draws attention to the possibility of epidemic diseases being spread by returning soldiers. He points out that after the Franco-Prussian war a pandemic of smallpox spread through Europe. In Germany alone, the disease is estimated to have caused the death of 170,000 persons. In England, where smallpox was conveyed by French refugees in 1870, the death rate increased from 0.7 per 10,000 inhabitants in 1869 to 1.2 in 1870, and 10.1 in 1871. It then declined to 8.3 in 1872 and 10 in 1873. From Germany smallpox spread into Austria and Bohemia. In Vienna the incidence rose per 10,000 inhabitants from 7.6 in 1871 to 52.7 in 1872; in Prague from 1.5 in 1870 to 39.7 in 1872. In the Crimean war the French Army carried cholera from Toulon and Marseilles to Gallipoli, and sporadic cases occurred at Nagra, Varna, and Adrianople. During the expedition to Dobrudja cholera broke out in explosive form, compelling the army to return. When the scene of war was transferred to the Crimea, cholera broke out violently. The total number of deaths in the French army during the campaign was 12,457, in the English army 4,531, and in the Piedmontese army 1,230. The total

combined strength of the troops is believed to have been about 262,000. From the Crimea cholera spread through Turkey, around the Black Sea, Greece, Smyrna, the Dardanelles, Constantinople and the Danube principalities. Typhus was also prevalent in the French army in 1855-56, and was epidemic in the Russian army and in southern Russia. It was also carried to England by troops and was epidemic there in 1856-57. The American Civil War was followed by an unusual prevalence of typhoid, dysentery, and smallpox. In the absence of reliable statistics, the extent of disease in the civil population cannot be stated. However, in Connecticut the death rate rose from 1.0 in 1863 to 19.0 in 1864, and declined to 16.0 in 1865. In Massachusetts it was 18.5 in 1862, 22.1 in 1863, 22.8 in 1864, and 20.6 in 1865. In Massachusetts it is estimated that 10,000 people contracted typhoid, dysentery or smallpox during the years 1863-65. After the Spanish-American War an unmistakable wave of typhoid fever spread over the United States. Some of the epidemics were of an explosive and highly sensational nature; for instance, at Ithaca in 1903 there were some 1,300 cases, or one in ten of the population, and about one in a hundred died. The following year there was an epidemic of 600 cases at Watertown, N. Y. At Butler, Pa., there were approximately 6,000 cases. Other epidemics occurred at Augusta, Me., in 1903, at Cleveland in 1903-4, at Columbus, Ohio, in 1904, at Lowell, Mass., in 1903, and at New Haven, Conn., in 1901. Moreover, the number of cases of typhoid increased throughout the country, and the death rate from this disease remained high for several years. The efficacy of precautionary measures against infection of the civil population was shown by the French after the Crimean War, who only allowed those soldiers to land from transports who had been entirely free from typhus for some weeks and placed suspected divisions of troops in detention camps, where the men were inspected, bathed, and reclothed, with the result that the disease was not communicated to the civil population. After the Russo-Japanese War of 1894-5 the Japanese employed a two-fold system for the elimination of infectious disease among returning troops. First, infected men were not allowed to join the transports bound for home. Second, quarantine stations were established. When the transports reached their destinations the men were divided into groups of sixty and sent to disinfection establishments, where they were bathed and their effects disinfected. Major Soper points out that such diseases as trench fever, typhus, relapsing fever, cholera, and plague, if once started, might produce great havoc. Most of them are transmitted by vermin, usually the louse, which certainly exists in America in congested districts and particularly among foreigners, and although its extermination among troops may be practicable, in the case of the great civil populations it is quite another matter. Cholera has been known to exist for some time in western Russia, Sweden, Spain, and Austria-Hungary, and it has recently been reported in Germany and France. It is also at Archangel, or near there. It is probable, therefore, that some of our troops are now exposed to infection, and although under present political and social conditions this disease should not gain a footing in this country, it must be remembered that the etiology of cholera and typhoid are practically identical, and in some parts of the United States typhoid is a very common disease. This, coupled with the fact that nobody is immune to the disease, would favor the spread of cholera, if once introduced. Local and unrecognized epidemics would occur at first and the disease would thus obtain a footing. It is well to remember that in spite of the attention paid to personal and domestic hygiene in this country, infantile paralysis and influenza have spread, typhoid is always with us, and pneumonia is on the increase. The safe attitude of mind to hold is one of caution, and it is most important that only persons well trained in public health work should adminster and teach the principles of sanitation and epidemiology. Boards of health should be soundly constituted as to their personnel and should be given sufficient funds to do their work; politics should be rigidly excluded from the administration of the public health. The young men returning from abroad have received a certain amount of instruction in personal hygiene and have learned many useful, and some painful, lessons during the war. They are capable of arousing considerable interest in public health work, and these possibilities should be utilized. Finally, efforts should be made looking to the prevention of unnecessary sickness and the promotion of health and efficiency on a higher plane than ever before.

7. Influenzal Intraabdominal Catastrophes. Reginald Eccles Smith.

7. Influenzal Intraabdominal Catastrophes.—Reginald Eccles Smith points out that during the recent epidemic of influenza several important abdominal complications have been observed. These may be divided into three classes, comprising those directly due to a specific bacillus, those due to associated toxemia, and those which are coincident and noted as a warning to the surgeon. In the early days cases were constantly sent in to the surgical section with the diagnosis of perforated gastric or duodenal ulcer, or less frequently acute appendicitis, or even empyema of the gall bladder. In almost all cases the onset was sudden; there was usually a history of malaise, followed by acute generalized pain in the abdomen, associated with generalized rigidity, often vomiting, a temperature two or three points above normal, and a running pulse. In a number of such cases there were no clinical signs in the chest to lead to a definite diagnosis. Careful observation showed that the rigidity and pain were not absolute, but in most cases was referred to the upper zone of the abdomen and in a minority to the lower zone, including the right iliac fossa. Pain and rigidity in the upper zone are referred along the eighth, ninth, and tenth intercostal nerves and are much more severe on that side of the abdomen which corresponds to the chest lesion either definitely present or appearing later. On two occasions Smith blocked the eighth and ninth intercostal nerves and symptoms disappeared. Less frequently the eleventh and twelfth intercostal nerves have caused the pain, and a perforated appendix has been closely simulated. Although they may not hold good in a superimposed surgical lesion due to and grafted on to the original influenzal infection, the following three points are of value in making a diagnosis: (a) The movement of the alae nasi. In cases of influenza with acute abdominal pain, even when no physical signs have appeared in the lungs and respirations are only slightly increased, if the alae nasi are working the condition is never abdominal. It only occurs in late true abdominal lesions when general peritonitis is well advanced. The movement of the alae nasi may not be very marked when the patient is recumbent, but can be elicited with a little exertion. (b) Dullness in the flanks is never present in influenzal pseudocatastrophes, except in class A, when it is an early sign. (c) The facies of the influenzal victim dominates the scene. The anxious, terror-stricken look of the true abdominal lesion is not present as a rule. The anxiety is more lethargic and resigned, and of the medical rather than the surgical type. The writer divides the true cases of acute abdominal catastrophes associated with influenza that have come under his notice into three classes: Class A includes infections of the general peritoneal cavity by organisms associated with the influenza epidemic. The infecting agent has always been the streptococcus, and, as far as can be stated, it is a blood-borne or embolic lesion and takes the form of an acute streptococcic general peritonitis. Class B includes cases of acute toxemic dilatation of the stomach. Class C, in which are placed coincident acute abdominal lesions occurring in the influenzal attack or during convalescence. Smith concludes with the following observations: (1) That

during the present epidemic of influenza the chest should become more the province of the surgeon than is usual and should be minutely searched for any physical signs when a suspected abdominal lesion arises. (2) The three points already put forward will be found of great assistance in such cases, and may save a laparotomy in a patient who is already not in good condition. (3) The infection of the peritoneum is blood-borne and is not due to direct extension through the diaphragmatic lymphatics. Streptococcic endocarditis is a jumping off ground for peritoneal infection, but is not necessarily always present. (4) Surgical interference so far has been of no avail, but it is not surprising when one studies the mortality in the present epidemic, in which as yet intra-abdominal lesions have not been recorded. (5) Discretion in dietary is very necessary in the toxemic types, as an overloaded stomach may become a danger. (6) Persistent vomiting in cases of influenzal toxemia should be regarded with suspicion. Although the evidence is as yet small, the condition of acute dilatation is proved, hence early stomach washing and the use of pituitrin may save a patient when a *laissez faire* attitude will certainly end in death. (7) The incidence of true abdominal catastrophes in a patient with influenza must always be kept in mind and suitable measures promptly undertaken.

2. Functional Paralysis of the Diaphragm in Two Cases with Acceleration of Respiration.—Alexander Watson and J. S. Meighan point out that attention has been directed recently to the rapid, shallow type of breathing in late cases of gassing, and that Haldane has associated the condition with an exaggeration of the Hering-Breuer reflex. The condition has also been observed in cases in which nervous symptoms have developed as the result of shell shock or other disturbance. Observations made by the authors upon two cases at Oakbank Military Hospital seem to indicate that a paresis or paralysis of the diaphragm, the result of functional disturbance of the center of the phrenic nerves, may account for the acceleration in breathing in some cases. In these cases graphic records of the chest and abdominal movements were taken. The tracings showed extensive and rapid movements of the chest, but only a very slight movement, a mere tremor, of the abdomen, which subsequent investigation clearly demonstrated was propagated from the chest. The authors consider it probable that the acceleration in rate was due to failure in the action of the diaphragm. No discomfort was caused by breathing at 75 a minute, but when the rate was increased to about 170 a minute it could not be maintained for any length of time. So long as it was maintained it showed no decrease in the abdominal movements. They refer to the cases reported by Gerhardt as having paralysis of the diaphragm. In one of these cases the patient breathed shortly and insufficiently for the needs of the voice. Faradic or galvanic treatment of the phrenic nerves was followed in some cases by improvement or cure. From a case reported by Cowan, however, and diagnosed as peripheral neuritis, it would seem that paralysis of the diaphragm is not necessarily accompanied by any marked increase in the rate of breathing.

6. The Occurrence of Morgan's Bacillus in Chronic Discharging Wounds.—Major Harold E. Whittingham draws attention to the fact that the dysentery group of the bacilli, including Morgan's No. 1 bacillus, has been repeatedly found associated with cases of asylum or institutional dysentery in England and that, therefore, a Poor Law infirmary is a likely habitat of these organisms. He points out that should this prove to be the case, institutions of this kind should not be used as general hospitals for troops, at least until they have been thoroughly cleansed and disinfected throughout. In a number of wound infections occurring in a Poor Law infirmary it was noticed that certain deep wounds, which were moderately clean on admission—*Streptococcus viridans* and *Staphylococcus aureus* and *albus* being found, and in one case *B. pyocyaneus*, and in another *B. perfringens*—gradually went from bad to worse in spite of careful treatment. These cases ultimately developed chronic discharging sinuses, the discharge having a peculiar odor like that of a bacillary dysentery stool. Blood cultures were negative. In six cases an organism was isolated from cultures made from wound discharges which was identical with Morgan's No. 1 bacillus. Twenty cases were then examined on admission, in none of which Morgan's bacillus could be isolated. The presence of this organism, however, was revealed later in five of these cases, the infection evidently being superimposed on the wounds. The pathogenic action of this bacillus in wounds was evidenced by the toxic condition of the patient and the chronicity of the suppuration as compared with similar wounds from which this organism was not recovered; also from the fact that under treatment with an autogenous vaccine prepared from this virus the general and local conditions markedly improved. The odor perceptibly diminished from the wound in three days, and within ten days a dull and apathetic patient would be up and cheerily smoking with his wound comparatively "clean." The source of the infection is uncertain, but it is probable that it may have occurred from the dust of the place. The question of non-sterile dressings was considered. Bacteriological tests all proved negative, and since cases occurred in surgical wards widely separated and attended by different medical officers and members of the staff, "carrier" infection was eliminated.

1. The Clinical Symptoms of Chronic Intestinal Stasis.—Arbuthnot Lane, after describing the mechanical aspect of chronic intestinal stasis, says that dealing with the toxic effects of the delay, beginning with the large bowel they may cause infective processes in its mucous membrane which are classified under the term "colitis." They begin in and about the iliac segment of the colon and tend to extend along its length. Cancerous ulcers develop more frequently in the portions of the colon where the feces are hardest. The infection of the mucous membrane may involve the appendix, which is often anchored and its lumen constricted by acquired bands securing it to the abdominal wall or to the mesentery of the ileum. The material that stagnates in the small intestine becomes infected with organisms which effect an entry into it from the cecum. The infection may extend up to the duodenum, and thence to the liver and pancreas along the ducts of these organs and produce inflammatory changes in their walls. Calculi may form which, besides producing obstructive symptoms, may by their irritative impact result in the development of cancer. It is obvious that any operations performed upon the gall bladder or on the ducts of the liver and pancreas are for conditions that are of the nature of end results, and by such a procedure alone no means are taken to deal with the primary cause of the trouble. In other words, the patient is not cured of the disease, though he is relieved from some of the symptoms to the extent of the surgical interference. The main points with reference to the radiographic aspect of chronic intestinal stasis are:

(1) The length of period that the meal remains in the stomach, the behavior of the stomach, the mode of emptying. (2) The size and shape of the duodenum, the mode in which it evacuates its contents, the form of the duodenojejunal junction. (3) The length of time the meal remains in the ileum, the mode of its evacuation, the degree of thickening of the walls of the terminal coil, the relation of the appendix to the end of the ileum, the evidence of the presence of an ileal kink. (4) The size and position of the cecum, with possible indication of its rotation. (5) The mode of passage of the meal through the large intestine, the limitation by a band of the caliber of the bowel about the junction of the cecum and ascending colon in the transverse colon, just below the gall bladder where the acquired ligament is attached, which connects the gall bladder to the pylorus duodenum, transverse colon at the splenic flexure, and at the last kink at the left pelvic brim. The form of the bowel must be examined with a view to determine the presence of inflammation of its wall or of diverticulitis. The shape and size of the pelvic colon should also be carefully observed both in the case of the meal and in that of the enema, since this is a factor of the greatest importance. The presence or absence of gall stones should be noted. In order to meet the prolapse of the viscera and the consequent angulation of the bowel at the several points at which it is fixed, great benefit may be obtained by pressure exerted on the lower abdomen in such a manner as to tend to keep the viscera up. An encircling belt does not do this effectually, since it serves to increase the intraabdominal tension by its lateral pressure. A stay increases still further this defect. On the other hand, the greatest advantage can be obtained from a support which acts on the lower abdomen only. The best form of support is that called the Curtis belt, which has been constructed for the purpose. It is of the nature of a truss, with a counter pressure behind and springs which control a central V plate. If paraffin is taken at a suitable interval before a meal, it precedes it in the way through the tract. It facilitates the passage of the intestinal contents through the several points where they are likely to be held up by a mechanical obstruction or by spasm of a reflex or inflammatory origin. It, therefore, tends to overcome the delay of the material in the small intestine and also to hasten the passage of feces through the large bowel.

1. Clinical Observations on the Early Stages of Trench Nephritis.—G. S. Strathy holds that although microbic infection is almost certainly the *sine qua non* of the disease, predisposing causes probably play an almost essential part. The disease was not existent in troops before landing in France or other theaters of war, and is not present in the civilian population in England, nor has it been heard of among the civilians in France and Belgium. It would therefore appear as if there is some great predisposing factor in the life of the army abroad which prepares the way for infection. It is striking that cases have not broken out in England due to infection from returned soldiers. The problem of the predisposing cause has given rise to many theories and suppositions. The epidemic was more prevalent on the western European front than on the other fronts, but occurred to some extent on all fronts. It was more common among the British than the French troops. It occurred among all arms of the service at the front and was not unknown among troops at the base. McLeod and Ameuille found that albuminuria occurred in a high percentage of troops in training in England. They found that the percentage of men having albuminuria was higher among British than French troops. The urea excretion was also higher among the British. Various theories have been advanced to explain these facts. Exposure and fatigue due to army life were suggested as the cause of so many men having albuminuria. Chlorinated water and immature beer were said to damage the kidneys. The author has found nothing to suggest that they were predisposing causes of epidemic nephritis. Several men were affected who were sleeping in warm, dry billets, and who had not done any heavy manual labor. Possibly the high protein diet of the British soldier predisposed him to attack. Records do not show age as a predisposing factor. Very few men were attacked during their first three months in France. Several Australians developed their first symptoms while on board ship coming from Egypt. While there is probably some relationship between epidemic nephritis and the high percentage of albuminuria found in healthy troops both in France and England, it is almost certain these cases of unexplained albuminuria were not mild cases of epidemic nephritis. It would seem likely that there was an extra strain thrown on the kidneys of the British troops which predisposed them to attack by a microorganism which was prevalent in the army abroad. The symptoms divide the disease into three main clinical types, namely: (*a*) Mild cases with albuminuria and few subjective symptoms; (*b*) hematuria cases with symptoms pointing to affection of the lower part of the urinary tract, and (*c*) nephritic cases with edema. These three main types cannot always be sharply differentiated, for mild or albuminuria cases may go on to the more marked type with edema, or hematuria and edema may be present in the same patient. With rest in bed and a simple diet of milk and milk puddings, the large majority of cases improved rapidly. The symptoms calling for active treatment are cough, dyspnea, decrease in urine, headache, and convulsions. If a patient was markedly edematous or his blood pressure high, a hot air bath was given. In nearly all cases this produced free sweating, relieved the cough and headache and decreased the edema. The patients' bowels were kept fairly free with Epsom salts, hut patients were not severely purged. If the dyspnea did not then subside and was severe, oxygen inhalations almost invariably gave considerable relief. Opium in any form for the relief of cough or sleeplessness the author abandoned after some unhappy results from its use. It appeared to increase the patient's cyanosis. For convulsions, spinal puncture and withdrawal of fluid was done in three out of four cases.

5. The Return of the Army Medical Officer.—E. J. Williams thinks that life in the army has not been an entire loss to the army officer concerned. His travel experience and sacrifice have broadened his vision in a way that will be of great value to him, although it cannot be measured in dollars and cents. His training in army work will benefit him directly in several ways. The necessity for recording the many details in connection with each case, both from the medical and military viewpoint, has given him an insight into the value of keeping accurate records. This training will assist him materially in connection with the business side of the profession and will insure greater satisfaction to the patients as well as himself. His experiences in the military hospitals have taught him the great benefits to be derived from the co-operation of the different services in the unit. This is possible owing to the commanding officer being supreme and the workers all full timed men pledged to fulfill his orders. This allows for a development of efficiency in a hospital never seen in civil life, where a medical superintendent always occupies a minor position. A host of medical officers have been carefully trained in *x*-ray work and sanitation so that the benefits of their knowledge might be spread over the country to places where at present they are unknown. The health officers should be of great assistance in the years to come if public health is given the attention that now seems probable. The esprit de corps developed among the men in the Medical Corps should be of great benefit to the profession on the absorption of the officers into civil life. They have been so long free from the petty jeal-

ousies that have always marred our esteem in the public eye that the foolishness of them all is only too apparent to them. Let us hope that they will use their influence to rejuvenate all our medical societies. The county, provincial and Dominion associations all have functions of equal importance. Until the county association reaches that point of efficiency which is required of every successful organization, the larger associations will be so much the weaker. The questions which concern the profession in the smaller towns and cities should be considered by the county associations, and then in turn brought before the larger associations. The futility of submitting local questions to the larger associations has been amply demonstrated.

Deep Radiotherapy in the Gynecological Clinic at Erlangen, Particularly from the Viewpoint of the Dosage of the Rays in the Treatment of Cancer.—H. Wintz exposes the principles of and facts obtained in very precise radiotherapy. Starting with the notion of "practical homogeneity" (that is to say, that the quality of the rays when sufficiently filtered can cause them to penetrate the tissues to the depth of ten centimeters without any waste of radiation along the tract), the writer has been able to estimate as follows the relative quantities of required irradiation:

Cutaneous unit (An arbitrary figure, corresponding to an erythema occurring within eight to ten days and to a mild brown pigmentation at the end of four to five weeks.)	100
Dose for sterilization	34
Dose for sarcomata	60-70
Dose for carcinomata	100-110
Dose supported by the rectum	135
Dose supported by the muscles	180

This dosage of precision has been established by experimental research work in which irradiation, after a filtration necessary for obtaining the "practical homogeneity," has been measured in depth (vagina, rectum) by an electrometer having an ionization chamber (Elektrometer mit Ionisationskammer). From the writer's figures it results that the ovarian tissue is three times more sensitive to the *x*-rays than the skin, and he has also been able to observe that the differences of the sensibility between the skin of one subject and another are much less marked than is generally supposed. The sensibility of different subjects only varies within the limits of from 10 to 15 per cent. (an exception is to be made in cases of nephritis, the skin in subjects with this affection being from 30 to 40 per cent. more sensible than in a normal person). The tolerance of the rectum is highly favorable for the treatment of carcinoma of this region, since the gut supports 130 per cent. of the quantity necessary for killing the neoplasm. The clinical results both in the treatment of pelvic tumors or amenorrhea have confirmed the justness of the writer's technical principles. Sterility can be brought about with absolute certainty with the irradiation of four fields (two for each ovary), the total duration of the séances being from 120 to 130 minutes. The writer also describes his methods of treating cancer. In cancer localized to the cervix uteri the process is killed with certainty with 110 units. More extensive neoplasms, such as gastric carcinoma, require larger quantities, not because the cells resist the rays, but because it is necessary to extend the zone of irradiation over the entire tumor. It must not be forgotten that an insufficient dose of the rays over a small portion of the neoplasm may have an effect contrary to the one desired, producing a more acute growth of the neoplasm.

A Note on Personal Experience in Radium Treatment.—I. Fabry has treated a total of 145 cases of cutaneous cancer, 185 cases of lupus, 70 cases of naevus, 37 cheloids, 7 cases of plastic induration of the penis and one case of Dupuytren's contracture with radium. In cancer it is better to first treat the lesion by galvanic cauterization and afterward use the radium. The results are far superior to any other form of treatment, not excepting radiotherapy. This curative action is not, however, evident in cancers having extended in depth and involving the periosteum or bone, but even in these circumstances the process may offer a certain remission while pain is controlled. In lupus many perfect cures are obtained in the early phases of the process, while some success is obtained in serpiginous lupus. Lupus of the nasal mucosa is more easily accessible to radium than to light and *x*-rays. In naevi the results are all the more rapid the younger the subject, while when the lesion is extensive years of treatment may be necessary. The results of radium treatment in cheloid have been good, and in the case of Dupuytren's contracture the outcome was really astonishing. In the cases of plastic induration of the penis the results were not so remarkable.

The Treatment of Peritonitis with Ether.—E. Seifert has experimentally produced peritonitis in cats by injecting the intestinal contents or pus derived from abscesses into the peritoneum. Intraperitoneal injections of ether had no influence on the peritonitis either as a prophylactic or curative measure.

Visceral Analgesia in Tabes Dorsalis.—A. Hanser relates the history of a patient who died from a generalized peritonitis resulting from a duodenal ulcer. The clinical symptoms, which were evidently insufficient for making a diagnosis, consisted in signs of general intoxication, while the abdomen offered few functional signs, all pain and rigidity of the walls being absent on palpation. The diagnosis went astray in the first place on account of the possibility of an intoxication (the patient was a chemist), and it was when it was known that the subject was tabetic that some visceral lesion was suspected. The writer particularly insists on the fact that the patient had never offered gastric crises, and discusses the indications that similar cases may give relative to the sensitive innervation of the abdominal viscera. The case also has a practical importance, since it shows that in a tabetic subject the most typical symptoms of an acute abdominal surgical case may be wanting, a fact not referred to in the textbooks.

Digestive Disturbances Due to Breast Milk Too Rich in Fat.—E. Slawik, basing his remarks on a large number of analyses of woman's milk, concludes that the fat content may attain a considerable amount (7 to 8 per cent.) in some women. The resulting disturbances in the infant are, above all, vomiting and anorexia and therefore interfere with the general nutrition. Constipation is often severe.

Bilious Peritonitis with Apparent Integrity of the Biliary System.—E. Koenig recalls the obscurity which reigns in the interpretation of this phenomenon. The three cases which he reports would seem to uphold the theory invoked, namely, a kind of filtration and diapedesis arising in the biliary tract. From the viewpoint of bacteriology the intra-abdominal exudate was found sterile in one instance, while in the two other cases the colon bacillus was found. As to treatment, cholecystectomy is the only rational means for overcoming the pathological process.

Wounds of the Joints.—F. Demmer, after giving some statistical data, is of the opinion that conservative treatment is not to be carried too far. Payer's method seems to the writer to be the best, namely, the prophylactic removal of the missile and other foreign matter, followed by drainage and injections of camphorated phenol.

Perforation of the Macula Lutea.—M. Salzmann studies the destructive atrophy occasionally occurring

(although very rarely) in the fovea following various forms of traumata. The diagnosis is made with a direct ophthalmoscope. The lesion is not due to a primary action of the trauma but to a slowly progressive process requiring a year or more to undergo its evolution. From his pathologic findings the writer invokes, in order to explain the phenomenon, an atrophic process involving only the retina, leaving the other ocular structures and pigment layer of the retina intact. It is a commotional phenomenon which brings about a necrobiosis of the most labile ocular tissue and the least capable of regeneration, viz.: the macular retina.

Extraction of a Shrapnel Bullet from the Internal Auditory Canal.—O. Beck reports the case of fracture of the petrous portion of the temporal bone, resulting in the unilateral loss of hearing, with vestibular reflexes and a complete facial paralysis. Localization of the bullet with the *x*-rays. Operation three months after receipt of the injury, by the mastoid route. Removal of the missile, recovery (naturally without a return of the functions).

Remarks on Influenza.—Tremolières and Rafinesque in the study of the grippe epidemic in a certain sector of the West Front saw at least three phases which were quite distinct. In May-June, 1918, they saw what might be termed a three or five day fever, beginning abruptly with slight chills, intense headache and general myalgia and lumbalgia, and fever up to 40 C., with in addition a certain measles-like syndrome of congestion of the face, conjunctival injection, lacrymation, coryza, and angina. In the great majority of such cases there was a quick turn for the better but in a minority there was a special syndrome suggestive of tuberculosis. Only in a small minority was there a complication of bronchopneumonia or pleurisy. Summing up this early outbreak the authors lay stress on the predominance of nervous symptoms, referring evidently to the element of pain and of asthenia. From the middle of June to the end of August a new phase of the malady asserted itself. The grippe had become less frequent but more deadly. Benign types were still in evidence but along with these were seen intense pulmonary congestion and pseudolobar bronchopneumonia. These two conditions were associated at times with pulmonary edema on the one hand and purulent pleurisy on the other. The third phase prevailed from the end of August to the middle of December. The virus had become increasingly virulent with passage. Bronchopneumonia increased in frequency and septicemia became more common. The author describes half a dozen clinical types encountered. In addition septicemia per se is separately discussed. The authors date the epidemic from May 1 or several weeks before the Madrid outbreak and trace it to December 10. During this period 1086 soldiers were interned for this malady. Of this number 100 succumbed to bronchopneumonia and septicemia, which is less than 10 per cent.

Hygiea.

A New Form of Radiation from the Human Organism.—Alrutz has investigated on two hysterical men the possibility that the hypnotist gives off from his person some unknown form of radiation when he makes passes over the bare hands and forearms of his subjects without actual contact. In these passes the finger tips are presumably involved, and especially when subjects are placed under hypnotic sleep it is known that both analgesia and contraction of muscles are at times developed incidentally. In general, however, all such phenomena have been attributed to suggestion or autosuggestion. In order to eliminate not only suggestion but any accidental influence due to heat or mechanical stimulation the author blindfolded his hypnotized subjects and fixed a pane of glass over one of the bared arms. The subject was in mild hypnosis and both hyperesthetic and hyperalgetic. Downward passes were now made above the glass, whereupon analgesia developed. These were followed by upward passes, whereupon sensibility became at first normal but with further action hyperesthesia and hyperalgesia reappeared. The same phenomena were obtained when metal was substituted for glass, but if cardboard or wood was used the phenomena were more or less in abeyance. The experiments were varied by placing a disk of wood over part of the glass in such a way that the hand was protected by both substances. Downward passes now showed that while the protected hand retained its sensibility the forearm became analgetic. Now other individuals who were substituted for the author obtained the same results with passes of the downward type, although they were unacquainted with the subject. If the subjects were in deep hypnosis and both anesthetic and analgetic, downward passes were without effect, but upward passes restored sensibility wholly or in part. The author also learned that if he pointed his finger or a glass rod toward a muscle, tendon or nerve, a contraction of the corresponding muscle occurred. The same result was obtained through a sheet of glass or metal. But few subjects tested refused to respond in a standard way to the above tests, so that the author believes that he has discovered a new form of emanation from the human body. He has also found that this form of radiation can be reflected and conducted like other forms. The experiments, while conducted at first on two hysterical subjects who could be readily hypnotized, have been successfully repeated on many others and even during wakefulness.

Influenza in Norway.—Ustvedt gives an account of this subject beginning with the earliest records. While Hirsch mentions 125 epidemics between the years 1173 and 1875, he has little to say of Norway, and our knowledge of the latter appears to be due to the account of the disease in that state in the nineteenth century by Hold. The oldest mentioned outbreak was in the winter of 1837, and then came outbreaks in 1847, 1857 and 1863. Nothing further is heard until 1889. In December of this year the pandemic reached Christiania and lasted until February of 1890. Of 10,461 victims but 24 succumbed to the disease. In 1891 the pandemic played a return date in April-May, and of 8,506 victims 118 died. In 1892, from New Year's to March, came the third visitation now having endemic qualities and claimed 4,000 victims with 62 deaths. In 1893 there were two "epidemics," one in the winter months and the other at the close of the year which apparently coincided with the cold period of the latter. The second episode lasted until February, 1894. The mortality was low. The affection had now settled down to ordinary winter grippe which apparently recurred annually with varying virulence. In 1906 the deaths numbered 138, which was considerably more than the average. It had become absurd to call this annual winter catarrhal fever by a name which was equivalent to the pandemic expression of the disease. It was now purely a domestic affair, one not brought in from without. True influenza does not require the winter for its development, for of Hirsh's 125 epidemics but 50 began in the winter months. However there is a parallelism which is difficult to explain away—for example the pseudo-cholera seen in both forms. The pandemic of 1918 reached Christiania on July 2 in a very mild form. In the epidemic hospital up to August 1, 128 cases were interned and 25 died. The author carefully analyzes this small material but gives no information as to the general outbreak nor in regard to the subsequent severe return of the plague.

Tannin and the Grippe Toxin.—Doulcet calls attention to the use of large doses of tannin in conditions due to bacterial toxins. The sole explanation is an affinity between this acid and the poisons referred to. Originally employed with benefit in tuberculosis, it has been tested in the Italian Army for influenza. The only result claimed is lessened virulence and a more favorable course. The dose, which is repeated at intervals, begins at 7 or 8 grams. By using this remedy one is able to avoid the abuse of antithermics.—*La Presse Médicale.*

Book Reviews.

THE PRACTICE OF PEDIATRICS. By CHARLES GILMORE KERLEY, Professor of Diseases of Children in the New York Polyclinic Medical School and Hospital; Attending Physician to the New York Nursery and Child's Hospital; Consulting Physician to the Babies' Hospital; Consulting Physician to the Sevilla Home for Girls and to the New York Home for Destitute and Crippled Children; Consulting Pediatrist to the Greenwich (Conn.) Hospital, to the Tarrytown (N. Y.) Hospital, to the Englewood (N. J.) Hospital, and to the Lawrence (Bronxville) Hospital; Ex-President American Pediatric Society; Ex-President New York County Medical Society. Second Edition, Revised and Reset. Price, $6.00 net. Philadelphia and London: W. B. Saunders Company, 1917.

THE position of Kerley in pediatrics is sufficiently well established to make welcome any contribution from his pen. The chief value of this work is characteristic of this writer; that is, it is intensely practical. He does not content himself with theorizing or generalities, but is always definite and exclusive. A valuable feature of the book is an appendix, which is in reality a handbook of materia medica and therapeutics for children. Kerley's book is probably the best single book on the subject for the general practitioner and will no doubt find a place in every pediatrist's library.

TRAITEMENT DES PSYCHONÉUROSES DE GUERRE. Par G. ROUSSY, J. BOISSEAU, et M. D'OELSNITZ. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1919.

THE six chapters of this work are devoted respectively to clinical aspects, causal factors, prophylaxis, treatment, nature and prognosis of the psychoneuroses of war. The types of disease encountered are chiefly psychomotor, including tremor and tics, the others comprising psychosensory, sphincteric and visceral disorders, and nervous crises. Psychomotor troubles may be general or located at different levels of the extremities, or in the head, neck, and trunk. The chief topics, as far as space is concerned, are treatment and speculation as to the intimate nature of these affections. The illustrations show the great predominance in the clinic of contractures, including clubfoot.

THE DIAGNOSTICS AND TREATMENT OF TROPICAL DISEASES. By E. R. STITT, A.B., Ph.G., M.D., LL.D., Rear Admiral, Medical Corps, U. S. Navy; Commanding Officer and Head of Department of Tropical Medicine, U. S. Naval Medical School; Graduate, London School of Tropical Medicine; Professor of Tropical Medicine, Georgetown University; Professor of Tropical Medicine, George Washington University; Lecturer in Tropical Medicine, Jefferson Medical College; Member, National Board of Medical Examiners; Member, Advisory Board, Hygienic Laboratory; Formerly Associate Professor of Medical Zoology, University of Philippines. Third Edition. Revised. With 119 Illustrations. Price, $2.00. Philadelphia: P. Blakiston's Son and Co.

THE previous edition of this capital little book was noticed in these columns less than a year ago. That edition was subjected to a very thorough revision, so the changes in this edition are but few. The subject of Trench Fever has been rewritten, and changes have been made in paragraphs of various sections. In many respects this book is a model of what such a work should be. It deals with its subject in a thorough yet concise manner; it is up to date; there is a pleasing absence of unnecessary padding; and the size and price of the book commend it to all students.

QUARTERLY MEDICAL CLINICS. A Series of Consecutive Clinical Demonstrations and Lectures. By FRANK SMITHIES, M.D., F.A.C.P., Associate Professor of Medicine, School of Medicine, University of Illinois; Gastro-enterologist to Augustana Hospital, Chicago. Volume I, Number 1, January, 1919. Annual subscription, $5.00. St. Louis: Medicine and Surgery Publishing Company, Inc.

THIS new periodical presents the bulk of the material shown before students at Dr. Smithies' clinic at the Augustana Hospital during the previous three months. Naturally some of the work is rather elementary, but that is to be commended rather than otherwise. One attractive feature is a section of Notes on Clinical and Laboratory Procedures which is appended to many of the case discussions. These are not only informing in themselves but show what methods were used in the cases presented. The cases are for the most part interesting and instructive and many physicians would benefit by a study of them. On page 68, in a note on the method of searching the stools for amœbæ, stress is laid on the method of obtaining the stool. It is probable that more satisfactory material may be obtained by the use of the proctoscope, and when the first specimen of stool shows no amebas the proctoscope should always be used. On page 62 there is a misprint. What is meant, of course, is "For a group III recipient, donors in either group *III* or IV may be used." If one may judge from the initial volume this new series of clinical lectures will be a welcome addition to current medical literature.

PHYSIOLOGY AND BIOCHEMISTRY IN MODERN MEDICINE. By J. J. R. MACLEOD, M.B., Professor of Physiology in the University of Toronto, Canada; formerly Professor of Physiology in the Western Reserve University, Cleveland, Ohio; assisted by ROY G. PEARCE, B.A., M.D., Director of the Cardiorespiratory Laboratory of Lakeside Hospital, Cleveland, Ohio; and by others. With 233 illustrations, including 11 plates in colors. Price, $7.50. St. Louis: C. V. Mosby Co., 1918.

THE object of this book is to bring into correlation the laboratory work of the medical student with his clinical work. Too frequently these are kept apart; the blame for this rests largely (but not entirely) on the teachers. Many of the standard text-books err in thus keeping apart what ought to be brought together. In this volume the authors have brought together such parts of the physiology and chemistry as are likely to be of value to the clinical investigator. The book is not a text-book on physiology, although a large part of its contents will be found in any modern work on that subject. At the same time, much that finds proper place in a work on physiology is omitted; hence the reader will find little or no mention of the muscle and nerve physiology, the physiology of the special senses and of reproduction. If the reader will take this volume as the authors intend it to be taken he will find in it much that will aid him in understanding the diseased conditions presented in the clinics, and also the modern methods employed in their diagnosis. The chapters are very short, and are also very readable; the book is well printed and contains a number of useful illustrations. Several of the borderland topics between the theoretical and practical aspects of modern medicine are discussed in detail; and such subjects as shock, starvation, hunger, control of body temperature and fever have special chapters devoted to them. There are also important sections dealing with the clinical applications of certain physiological methods, which show the value of some of the modern methods used in diagnosis and at the same time explain the principles involved in their use. The general practitioner who can find nothing instructive in this work is an unusually well equipped man.

BEVERAGES AND THEIR ADULTERATION, ORIGIN, COMPOSITION, MANUFACTURE. NATURAL, ARTIFICIAL, FERMENTED, DISTILLED, ALKALOIDAL AND FRUIT JUICES. By HARVEY W. WILEY, M.D., Author of "Foods and Their Adulteration." With 42 Illustrations. Price, $3.50. Philadelphia: P. Blakiston's Son and Co.

THIS book purports to give definite information concerning not only alcoholic beverages but also those forms of drink which will be to a large extent their substitutes, fruit juices and so on. Such beverages as coffee, tea, cocoa, and chocolate are likewise adequately dealt with, and much space is given to a consideration of water, which Dr. Wiley hopes will come into more general use. It is a fact that a great deal of adulteration of beverages takes place, and it is equally obvious that it is against the public weal in every way that this should happen. This work may serve the purpose of ending these practices somewhat and, in any event, knowledge of this kind is of great value.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 6, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged by the Committee on Public Health of the Academy.

Program of the United Public Health Service, with Relation to Venereal Control Among the Seamen of the Merchant Marine, New York Harbor.—Dr. W. A. WILSON, Acting Assistant Surgeon of the United States Public Health Service, spoke on this subject. He explained that under the Public Health Service there were a number of bureaus, such as the Quarantine and Marine Hospital, and that recently the Bureau of Venereal Diseases had been established. Under the Chambers-Channing bill $1,000,000 had been appropriated for the work of this bureau, which was to be apportioned among different States, where subsidiary divisions of this bureau were being established which would cooperate with the various State health departments. Of this fund the share of New York State was $99,090.89. Before the war the Marine Hospitals were prepared to care for the men in the United States Merchant Marine, but then many of them were on the deep seas; since the declaration of war many of these seamen were in the harbors and hospital accommodations for them were inadequate. The speaker had been sent by the Public Health Service to make a survey of hospital conditions and to see what could be done in the way of providing for the care of merchant marine seamen at this port. The verified figures of the survey which he made showed that the week of the survey 10,000 merchant marine seamen were shipped at this port; 499 transports were docked with an average crew of thirty men, and twelve passenger steamships with an average crew of 400 men were docked. It was found that there were also operating in the harbor 360 tugboats, the crews of which averaged five men, and 1,000 barges with one man to each barge. Thus it might be seen that there were some 25,000 men coming and going about the waterfront of this port, and in addition the Longshoremen's Union showed a membership of 15,000 and the Stewards' Union a membership of 1,000. In connection with these figures there were certain peculiar features that had to be taken into consideration in working with these men who lived on the sea and about the waterfront. The deep water seaman was a peculiar individual in that very often he would not go more than a few blocks from the dock, and even if not sleeping on the boat would return to it several times during the day or evening. In these localities about the only places open to him were the saloons and bawdy-houses. Of the 10,000 merchant marine seamen in this port every night it was estimated that at least 5,000 were infected with venereal disease, and as many as 800 were in the active infectious stage and should be in bed, but were on the streets of the city with possibly a temperature of 103° or 104° F. The Marine Hospital Service took care of American Merchant Marine seamen only, and these constituted only about 21 per cent. of the 10,000 seamen shipping at this port. These men could not be properly cared for because there were insufficient hospital accommodations for them. The Marine Hospital on Staten Island had accommodations for about 200 and was planning for an addition at the time the influenza epidemic broke out. The urgent demand for accommodations at that time so overtaxed the hospital that many venereal cases were turned out; not a great deal had been done since that time in the way of providing increased hospital accommodations for this class of cases. At the Barge Office, 313 East Nineteenth Street, they were caring for cases of venereal disease, but the work was a great burden, as they were already overworked by the duties imposed in connection with the War Risk Insurance. Another institution operating in this port was the Seamen's Church Institute, the only institution of its kind in the United States. This organization cared not only for the seamen of the American Merchant Marine, but of those of other nations as well. It had a capacity of fifty beds. The first day this organization opened its clinic there were 145 patients and of these 105 were coming back for continuous treatment. The worst part of venereal diseases came from the Spanish firemen and seamen in general. These men had been requested by the President to remain in the Merchant Marine, but were not allowed to enlist. It was also to be remembered that these men of the Merchant Marine had done great service for the country, there being perhaps no class of men in the service who had seen more periscopes than the seamen of the Merchant Marine. It might also be mentioned that there were 1,000 young Russians who struck this port and many of them had syphilis. In Russia syphilis was a family disease, the morals of the Russian people being about as high as the morale of their army. It was probably a rather broad statement to make, but it was the speaker's belief that 7 per cent. of syphilitic infections were accidental and if they could prevent accidental civilian infections they would have done a wonderful work. The first survey which the speaker had made revealed the fact that only four clinics in New York City were conforming to the regulations of the Sanitary Code in regard to the care and treatment of venereal cases. A later survey showed that there were ninety clinics in New York that were treating venereal diseases and that possibly an increased proportion were conforming with the sanitary regulations, but the facilities they offered were still entirely inadequate to care for those afflicted with venereal disease. Facilities of the outpatient department should be backed by beds in order to make it possible to detain those men in the active infectious period until danger of communicating the disease had passed. It was expecting a great deal of the War Department that it should hold and treat all these cases of venereal disease. The problem was a local one when looked at from the broad point of view. The records of the War Department showed that in the first draft in the State of New York 47,000 men were found to be infected with venereal disease. Between April, 1917, and September, 1918, those drafted into the army and found to be infected numbered at least 2,295,000. Since these men had brought this infection into the army from civil life, it scarcely seemed just that the War Department should have to detain and treat them. The problem was one that concerned the civil population, and would be a tremendously important one during the reconstruction period, since it involved the entire industrial efficiency of the nation. Much would depend upon the advertising policy of the newspapers, magazines, and medical journals. As the campaign against venereal diseases which was now being launched gradually progressed, the public would turn to the medical profession for advice and guidance, hence it was incumbent upon physicians to familiarize themselves with the program of the United States Public Health Service. They should avail themselves of the splendid volume of literature issued by the Bureau of Venereal Disease Control in Washington and with that issued by the local bureaus connected with the State health departments. This literature included not only matter intended for the profession, but much intended for the education of the public, including pamphlets for boys for girls, for expectant mothers, for parents, etc.

The Venereal Disease Problem from the Public Health Standpoint.—Dr. LOUIS I. HARRIS, Director of the Bureau of Preventable Diseases of the New York City Department of Health, presented this communication in which he stated that the venereal disease problem was one of the oldest in the history of mankind. Its only new feature was that it was no longer the exclusive subject of interest and study of the religious the ethical, and the medical leaders, and of a scattered few who were looked upon as violating the canons of good taste and polite breeding by public discussions of the problem. This publicity was not only an index of progress, but it might be regarded as prophetic of a profound and far-reaching influence in bringing about an acceleration in measures for the reduction in prevalence of venereal diseases. The awakening of the interest of the medical profession was a significant and important sign of the change in the attitude of society

as a whole toward this problem, a change which might in a large measure be attributed to the facts revealed by the condition of our army in the war, and by measures which were elaborated by our medical officers for their protection. The signal achievement of the medical guardians of our army and navy must not and would not end with the war. The public health service of the community had a distinctive place in the program for the prevention and supervision of cases of venereal diseases. We had now come to understand it. In so far as the general public was concerned the prime duty of a health department was to lead an unrelenting and vigorous campaign of education which, so far as was practicable, should begin with the young and be carried into every division or group of the community which might be benefited by proper instruction. The health department should combine with social agencies in the city to provide for wholesome and well planned recreation that would give an outlet to turbulent emotions and thought and furnish healthful distraction to the young, and, being advised of the viewpoint of the best informed and most progressive leaders among educators and physicians, it should direct and counsel or stimulate our high school authorities, parents, and others in proper methods of sex instruction. The public authorities should require the reporting of all cases of venereal disease, so as to make possible an intelligent and sane plan of action to safeguard the community from sources of infection that would otherwise be uncontrolled. The veiled diagnosis made by physicians out of solicitude for the feelings of the patient was out of date and a menace to many in the community. The provision of laboratory facilities by health authorities for the diagnosis of venereal diseases was not only an aid to those who could not afford to pay for such work, but while it assisted the private physician materially in his work among those of limited means, it was an oblique method of obtaining reports of venereal disease cases. The fact that all reports of venereal diseases were held confidential by the health authorities and, further, the growing tendency toward that cordial, cooperative, and necessary relationship between private physicians and health officers, should make in increasing measure for the full reporting of venereal disease cases. The health officer should stand in especially close relationship to those who were affected with venereal disease, and to persons who suspected they were affected, or who desired information and who would resort to the advertising "specialist" so-called, or develop various neuroses for lack of an authoritative guide and adviser. The Health Department of the City in 1914 established a medical advisory station to meet this need. In its brief career this Medical Advisory Service, conducted by Dr. Barringer, had advised 14,953 persons up to the beginning of this year. From 1914 to 1918, inclusive, 3277 persons presented themselves who were suffering from non-venereal diseases such as psoriasis, sycosis baræ, scabies, acne, various forms of eczema, furunculosis, purpura, vaginitis, and cystitis. Many of these undoubtedly were prevented from falling into the hands of advertising quacks and so-called "specialists" and directed to their family physicians and well conducted clinics according to their means. In fact, 861 of these persons had previously been under the care of quacks and were attracted to the Health Department clinics by the advertisement placed next to those of advertising quacks in newspapers which carried such matter. The information which the health authorities might glean from the full reporting of venereal diseases should lead to a program which would enable those authorities to give physicians help for those patients who needed special hospital care, or to follow up in a judicious manner those cases which drifted from under the care of private physicians or dispensaries after inadequate courses of treatment and which constituted a source of community danger. Dr. Harris showed that the number of hospital beds for venereal disease cases now available in this city was negligible. This lamentable condition called urgently for correction. At present, by virtue of the newly enacted State laws, in this city they had provided hospital beds at Riverside Hospital only for those who were convicted on the technical charge of vagrancy, which was really defined as prostitution or immoral practice punishable by law. The law-abiding citizen who might be in most urgent need of hospital care was practically offered no relief. The general hospitals and the infectious disease hospitals, should, it seemed to him, amply provide for the care of those in need of such accommodation. There was also a broad field for follow-up work which was now being recognized as a fundamental feature of dispensary service and of public health work in connection with the work of the venereal clinics. Although regulations establishing standards for the proper conduct of venereal clinics were enacted in December, 1917, there were at present scarcely more than a dozen of the nearly eighty in this city which conformed to these standards in all essentials. The strict enforcement of proper standards for the conduct of genito-urinary clinics, under penalty of closure when they failed to respond to good counsel and persuasion, should be insisted upon by health authorities. The provision of an adequate number of night clinics for the treatment of the venereally diseased was also urgently needed. Chapter 264 of the State Law of 1918 required that treatment be furnished free of charge by the local health agency to all persons suffering from venereal disease subject to subsequent investigation as to their financial status. This requirement would, it was to be hoped, be met by public health authorities throughout the State. Dr. Harris said it seemed to him that we might profit by the excellent results obtained by the army through its prophylactic stations where preventive treatment was administered to all applicants within a few hours after exposure. It seemed to him incumbent upon health authorities to maintain such prophylactic stations as a routine part of their work for those who could not secure this treatment promptly at the hands of a private physician. The Health Department in connection with its periodic examination of food handlers had laid the foundation possibly of a type of periodical examination which not only served to protect the public from food handlers in an actively infectious condition, but might also be the means of educating a considerable number of persons in relation to the prevention of venereal diseases. If this work could be logically extended through occupational clinics, conducted for the benefit of industrial groups, signal achievements in the prevention of disease, and of venereal infections particularly, might follow. Dr. Harris also made a preliminary report of their work in connection with the enforcement of Chapter 264 of the Laws of 1918. In a period of seven and one-half months, ending December 31, 1918, the Venereal Disease Division of the Bureau of Preventable Diseases examined a total of 2,070 women who were classed as convicted or suspected persons. Among these they found a positive Wassermann in about 37 per cent. About 12 per cent. of the women gave a positive gonorrhea complement fixation test, and in 9 per cent. the smear was positive for the gonococcus. Of 182 women who have definite evidence of clinical gonorrhea a positive gonococcus smear was obtained in only 25 per cent. The total number who gave evidence of gonorrhea or syphilis or both was approximately 58 per cent. A number of these women received a vigorous course of treatment and a considerable number were now in the care of Riverside Hospital.

Recent Legislation in New York State, Relating to the Control of Venereal Disease.—Dr. J. S. LAWRENCE, Chief of the Bureau of Venereal Disease of the New York State Department of Health and Assistant to the Surgeon-General of the United States Public Health Service presented this subject. After expressing regret that Dr. Biggs could not be present, he said he would tell of the legislation that they had been able to use. In the first place, they now called these diseases syphilis and gonorrhea and not venereal diseases. The State Department of Health was following up these diseases throughout the State and giving them no quarter whatever. The first law directed toward the control of these diseases was passed May 16, 1917, and was a part of the Domestic Relations Law, Chapter 205. It provided that applicants for license to marry must make affidavit to the effect that: "I have not to my knowledge been infected with any venereal disease, or if I have been so infected within five years

I have had a laboratory test within that period which shows that I am now free from infection from any such disease." That was the beginning of legislation for the control of syphilis and gonorrhea and appeared to be a very innocent law. In application it had proved to be just as innocent, as it had in a large measure miscarried. The reason for this was that most of the applicants for marriage license did not know what the diseases were; this was true also of some of the county clerks. The next measure was Regulation 29-A of the Sanitary Code, which spoke of chancre, gonorrhea, and syphilis as dangerous diseases, and made provision for furnishing circulars of information which instructed persons as to the precautions to be taken to prevent the spread of these diseases. It urged upon physicians the necessity of telling patients affected with these diseases the nature of their ailment and how to prevent its communication. This was the most delicate and difficult part of the problem. The department received many letters asking for a description of the diseases, what the symptoms were, or describing symptoms and asking whether the writer of the letter had a venereal disease. The provisions of this regulation could be carried out more fully in the future than they had been in the past. In the future the physician would have to speak more frankly to the patient in reference to these diseases for two reasons, first, because that was the best way to attack the problem and, second, because the patient would demand it. On September 1, 1917, another measure was enacted, known as the Avertising Law, Section II, 42-A, which aimed to prevent the treatment of venereal diseases by any but licensed practitioners of medicine. This measure was evaded by so wording advertisements that they did not come under the law and yet their meaning was perfectly clear. One advertisement carried the picture of a man receiving a salvarsan injection. The druggists of the State were not treating these diseases and the drugs formerly sold by them for the treatment of these diseases were gradually disappearing. A representative of the Druggists' Association came to the speaker and discussed this law, stating that they could be depended upon to a man to enforce it. The next regulation affecting the control of venereal diseases was in the form of an amendment to the Public Health Law, in relation to the reports of communicable diseases, which went into effect April 10, 1918. This amendment was a part of Chapter 177, Paragraph 25, and read as follows: "Whenever an examination for diagnosis by a laboratory or by any person other than the physician in charge of the person from which the specimen is taken discloses the existence of a case of infectious and contagious or communicable disease, the person in charge of such laboratory or the person making such examination shall immediately report the same, together with all the facts in connection therewith, to the Health Officer of the city, town or village from which such specimen came, and shall keep a permanent record of all the facts in connection with such examination, including the identity of the person from whom the specimen is taken and the name of the physician, if any, sending such specimen." In commenting on this measure, Dr. Lawrence said that venereal diseases were not reportable in the State of New York except where the people had made them reportable. In some communities they were reported by number and in others just as diphtheria or typhoid fever would be reported. An amendment to the Sanitary Code, which became effective on August 1, 1918, Chapter II, Regulation 2-A, provided for reporting cases of communicable disease by physicians and for submitting specimens for laboratory examination in cases of syphilis, gonorrhea, and chancroid. Regulation 2-A, entitled "Submitting Specimens for Laboratory Examination in Cases of Syphilis, Gonorrhea, and Chancroid," read: "It shall be the duty of every physician to submit promptly to the laboratory of the State Department of Health, or to a laboratory approved by the State Commissioner of Health for this purpose, such specimens for laboratory examination and such data relating thereto as may be prescribed in the special rules and regulations issued by the State Commissioner of Health from every person affected with any one of the communicable diseases mentioned in Regulation 1, Group B, or from any person in whom suspicion of such disease exists." Regulations 29-A, 29-B, 29-C, 29-D, and 29-E of Amendments and Additions to the Sanitary Code, which became effective on August 1, treated of the instruction of persons affected with syphilis, gonorrhea, or chancroid; records of cases of syphilis, gonorrhea, and chancroid not to be disclosed; occupations forbidden to persons affected with syphilis or gonorrhea in the infective stage; reporting persons violating laws and regulations concerning syphilis, gonorrhea, and chancroid; duties of physicians and others under the public health law concerning syphilis, gonorrhea, and chancroid. Chapter 264 of Health Legislation added two new sections, 343-M and 343-T, which gave to health authorities the power to examine any person reasonably suspected of being infected with venereal disease and provided for the isolation and treatment of such persons. There had been some question as to how the Department of Health could legally enforce this measure, but a magistrate showed how it could be done by reversing the order of procedure. If a Health Officer had reasonable grounds for suspecting an individual to be affected with a venereal disease, he could submit his reasons to the magistrate, who after looking them over and finding them satisfactory could issue an order requiring the individual to submit to examination. If the affected person did not comply, he could then be arrested and brought into court, but they had little need to resort to this procedure, as most persons were perfectly willing to undergo treatment. Another of these new laws in Health Legislation was Chapter 342, which was passed on April 30, 1918, and provided for the creation of a Bureau of Venereal Diseases in the State Department of Health. The bureau was authorized by this measure to buy, manufacture, and dispense remedies for the treatment of venereal diseases, to examine specimens submitted to it, to make all necessary tests, to provide and distribute literature, and to use such other means as might seem desirable for the instruction of the public. Attention was also directed to Article 17-B of Chapter 264, 343-O, which related to the treament required for those found to be infected with venereal disease. This section required that any person suffering from any infectious venereal disease should be required by the Board of Health or the Health Officer of the district in which such person resided to conform to all the rules and regulations made and approved by such Board of Health or Health Officer for persons so diseased, such rules and regulations, except for the City of New York, to be first approved by the State Department of Health. This section made provision for carrying out further details of isolation and treatment. In closing Dr. Lawrence spoke of a measure which was to be introduced into the present Legislature, asking that Valatia State Farm might be used as a sanatorium for girls who had for the first time been brought into court; here they might be exposed to social service influences, instead of being committed to a reformatory for a first offense.

Dispensary Treatment of Syphilis in New York City.—Dr. JOHN A. FORDYCE presented this phase of the subject, in which he stated that our modern accurate knowledge of syphilis had been made possible by diagnostic and therapeutic methods developed during the past ten years, supplementing the accumulated clinical experience of previous generations. Syphilis was a problem of even greater importance than tuberculosis. It caused more race deterioration, shortened life and produced incurable imbeciles and helpless cripples In cities it was estimated that 25 per cent. of individuals affected with it died of heart disease and that in all necropsies performed from 6 to 10 per cent showed residua of syphilis. Insurance statistics gave the mortality among the victims of the infection as 68 per cent. higher than among those who escaped it The relation of syphilis to all branches of medicine was so intimate and for its mastery such highly technical knowledge was required that a new specialty was rapidly springing up to meet the requirements of our public institutions to do justice to this unfortunate class. As a result of such specialized teaching we now had in charge of many of our outdoor clinics men well versed in the required technical knowledge, who employed more or less uniform and standardized method

in the diagnosis and treatment of the disease. The medical profession as a whole and the public had yet to learn that early efficient treatment, accurately controlled by serological tests, could cure a large percentage of cases of syphilis in the early period of the infection and prevent the late high mortality from cardiovascular disease and the numerous cases of neurosyphilis, many of which became a charge to the community or the State. It was in the early florid stage that foci were established in the heart and aorta, the viscera, and the nervous system, which only after years produced incurable degenerations. Some syphilographers of reputation refused to recognize the significance of a persistent positive Wassermann reaction unless some clinical evidence of the disease was present. They overlooked or were ignorant of the fact that organs might harbor the spirochetes for years before showing functional impairment. It could not be too strongly emphasized that a positive Wassermann reaction meant the presence in the body of active or potentially active spirochetes. An outdoor clinic which did not control its treatment of syphilis by repeated tests of this kind was a failure in its duty to the patient and to the community. In cases of mixed infection, intraurethral chancres and others of uncertain character, a dark field examination or proper staining method for demonstrating the organisms was imperative. Every modern dispensary should be provided with a dark ground microscope and the services of an assistant capable of making the necessary examinations and interpreting the findings. A diagnosis made when the initial sore appeared followed by energetic treatment along modern lines insured a cure in perhaps 75 per cent. of such patients within the first year with a minimum amount of treatment. The physician in charge of a syphilitic clinic should be a dermatologist or at least have sufficient training in that branch of medicine to diagnose doubtful eruptions. The often disputed question as to which department in an outdoor clinic should treat syphilis would best be answered by the statement that syphilis should be under the care of one who had the necessary knowledge to grasp the problem. He must attack the disease from many angles and visualize it in its relation to medicine, surgery, neurology, ophthalmology, and, in fact, to all the branches of the healing art. Syphilis should be treated in one department in our outdoor clinics, provided with the necessary equipment for diagnosis and therapy. The department should work in close cooperation with other departments in the clinic so that early diagnoses might be made of complications in the heart, nervous system, and the eye. A number of beds should be available in the clinic or a nearby hospital, where lumbar puncture might be performed and intraspinal treatment carried out in cases which called for it. Syphilitic or cardiovascular disease required at times hospital treatment and rest. Few syphilitics, however, required prolonged hospital care. Special hospitals, except for the treatment of neurosyphilis, might only exceptionally be required. It would be difficult to persuade patients with fresh infections to frequent such institutions because of the stigma that would be attached to them. A modern institution, well endowed and equipped for research work in syphilis, would be of distinct aid in training men to perform subsequent clinical work along the lines indicated. It was difficult to retain men in our clinics after they had acquired a working knowledge of the disease unless facilities were afforded them to work on some of the problems of the disease. Scientific investigation should therefore go hand in hand with clinical work so that the interest of the staff personnel might be kept alive. Cooperation on the part of the patient was equally important and could best be secured by informing him of the possible consequences of his infection. Delinquents should be visited by a social worker. At the Vanderbilt Clinic patients with syphilis were first seen in the skin department and then transferred to the syphilis division, where blood for the Wassermann was taken and various clinical investigations carried out. Patients with demonstrable manifestations or a positive Wassermann were treated on the day of the first visit with mercury or, if contagious lesions were present, with salvarsan; others awaited the results of the various examinations. Every patient received an ophthalmic examination, heart examination, uranalysis, neurological examination, and before, during, or after treatment a lumbar puncture. Treatment was carried out systematically in courses of salvarsan and mercury, at weekly or shorter intervals, with mixed treatment or iodide of potassium as indicated, and was controlled by the Wassermann reaction. The patient was discharged as cured if his Wassermann was negative for a year and remained so after a provocative injection of salvarsan, and his spinal fluid was negative. Where involvement of the central nervous system was present intraspinal medical treatment was administered. In the annual report of the clinic from May, 1916, to May, 1917, the new patients numbered 2,895, of whom 34 per cent. were treated for syphilis; 1,893 Wassermann examinations were made; 3,229 intravenous injections of salvarsan were administered; 6,706 intramuscular injections of mercury, and 245 intraspinal treatments were given. In addition there were 224 lumbar punctures for diagnosis. Dr. Fordyce also presented the statistics of the clinic for the past year. He said he had investigated twelve of the best known outdoor clinics in New York and Brooklyn and found that the treatment employed by all consisted in courses of mercury and salvarsan or its equivalents. In only one of these was lumbar puncture performed; nine were equipped with a dark field; ten had access to Wassermann laboratories; six had a special social service worker; all charged the patient the actual cost of the salvarsan, or a slight excess to establish a fund for free salvarsan for patients who could not afford to pay for it, and to cover part of the cost of maintaining the clinic. Changes in the personnel of the dispensary staffs not infrequently interfered with continuous good work. The solution of this difficulty might be brought about by a salaried medical director of the clinic responsible to the trustees or medical staff. Dr. Fordyce also emphasized the importance of keeping accurate records and thought a plan for the standardization of treatment should be worked out. The men in charge of syphilis clinics should meet to discuss the problem and attempts should be made to have methods of therapy more uniform. In clinics where proper equipment was lacking and skilled physicians were not available patients should be referred to dispensaries where they could receive adequate treatment instead of being retained and given mercury or salvarsan in a haphazard fashion.

Dispensary Treatment of Gonorrhea in New York City.—Dr. B. S. BARRINGER read this paper, in which he reviewed briefly the history of the Associated Out-Patient Clinic of the City of New York. This body held its first meeting in February, 1912, and shortly after that meeting the Executive Committee of the Section on Genito-Urinary Diseases, Skin Diseases, and Syphilis drew up certain uniform standards for the treatment of both gonorrhea and syphilis in the out-patient clinics of New York City. In 1913 a survey was undertaken to see how many clinics in Manhattan had come up to the requirements set by the Associated Out-Patient Clinics of New York. At that time all the clinics in New York in which syphilis and venereal diseases were treated were visited. There were twenty-seven clinics where syphilis was treated, and of these seven were approved and twenty disapproved. Of twenty-six venereal clinics, but four came up to the requirements. Following this survey, it was thought advisable to add a few further recommendations to those of the Associated Clinics. These were: that clinics be opened at least three days a week; that a simple method of filing be adopted which would make readily available such important information as the number of patients, number of visits per patient, number of patients discharged as cured, and the number receiving treatment unimproved; that recommendations of the section of the Associated Out-Patient Clinics be framed in clinic rooms, and, that a uniform method of discharging gonorrheics be adopted which should include a complement fixation test. From 1913 to 1916 not much was done. Another survey was made in 1917, when it was found that there were still many clinics that were not up to the standard. On July 31, 1917, the Board of Health added to the Sanitary Code "certain regulations governing the conduct and maintenance of dispensaries wherein human beings infected

with gonorrhea or syphilis are treated or cared for." These regulations were in the main those of the Associated Out-Patient Clinics with some changes made by the Advisory Committee on Venereal Diseases of the Department of Health. At that time the opinion was given that the Department of Health had plenty of authority to close up any clinics which they considered did not come up to these regulations. As to the conditions at the present time, all that they knew was that many of the clinics were very bad. Dr. Barringer declared that the time for recommendations and surveys was past and the time for action was or should be at hand. He offered the following suggestions as to the methods which might bring all the Venereal and Syphilis Clinics of New York City up to the standard set by the Sanitary Code: (1) The matter of the inspection of clinics should be taken out of the hands of the regular Department of Health inspectors and put into the hands of men specially trained in that work. The Department of Health had such men on its staff. (2) Greater publicity should be given to the regulations of the Sanitary Code, so that every doctor of a clinic knew them by heart. Publicity should be given to the clinics complying with the regulations of the Sanitary Code and finally to clinics which did not comply. The Department of health had a medium in its *Weekly Bulletin* to further this. (3) There should be means of intercommunication between the Department of Health and physicians in charge of clinics. This might be best met by a committee similar to the old Advisory Committee on Venereal Diseases to the Department of Health. The old committee did excellent service in carrying the ideals and wishes of the clinics to the Department of Health, but failed somewhat in not carrying the point of view of the Department of Health to the various clinics. Such a committee could aid in the interpretation and carrying out of the regulations of the Sanitary Code. Dr. Barringer believed that the Department of Health and an Advisory Committee, working together with the Chiefs of Clinics, would make for a more ideal interpretation of the regulations of the Sanitary Code and for more efficient venereal clinics.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TEXT-BOOK OF PATHOLOGY. By FRANCIS DELAFIELD, M.D., and T. MITCHELL PRUDDEN, M.D. Revised by FRANCIS CARTER WOOD, M.D. 1243 pages. Illustrated. Price, $7.50. Published by William Wood & Company, New York.

ESSENTIALS OF SURGERY. By ARCHIBALD L. MCDONALD, M.D. 254 pages. Illustrated. Published by J. B. Lippincott Company, Philadelphia.

SPEECH TRAINING FOR CHILDREN. By MARGARET F. BLANTON and SMILEY BLANTON, B.S., M.D. 256 pages. Published by The Century Company, New York.

THE EARLY TREATMENT OF WAR WOUNDS. By H. M. W. GRAY 275 pages. Illustrated. Published by the Oxford University Press, American Branch, New York.

THE OPERATIVE TREATMENT OF CHRONIC INTESTINAL STASIS. By Sir W. ARBUTHNOT LANE, Bart., C.B. 328 pages. Illustrated. Published by the Oxford University Press, American Branch, New York.

ELECTRICITY IN MEDICINE. By GEORGE W. JACOBY, M.D., and J. RALPH JACOBY, A.B., M.D., 580 pages. Illustrated. Price $5.00. Published by P. Blakiston's Son & Company, Philadelphia, Pa.

SIXTH ANNUAL REPORT OF THE COLLIS P. HUNTINGTON MEMORIAL HOSPITAL FOR CANCER RESEARCH. 56 pages. Published by the Harvard University Press, Boston, Mass.

THE SURGICAL CLINICS OF CHICAGO. February, 1919. Vol. III, No. 1. 236 pages. Illustrated. Price $10.00 and $14.00 per year. Published by the W. B. Saunders Co., Philadelphia, Pa.

Miscellany.

Sanitary Condition of Lille During the German Occupation.—Calmette states that the sanitary condition of this city as a result of the German occupation was deplorable. Privation and subalimentation have been maintained over a long period. Before the war the population was 220,000. This figure has shrunk one half, largely as a result of the exodus of many people—about 60,000—and of the conscription of 25,000 of the young people. The mortality before the war was about 20 per 1,000 while at the present it is two fold that figure. This increase is attributable to the increase in tuberculosis, heart disease, dysentery, scurvy, and other states due to underfeeding. Only the infant mortality escaped this increase because the mothers did not work in the factories during the war and were also forced to nurse the babies because cow's milk could not be obtained. Adolescents show stunting and youths of 15 and 16 have the appearance of boys and girls of 12 and 13. The girls show retarded menstruation.—*Gazette des hôpitaux.*

Death of Miguel Pereira.—Nearly the entire issue of the *Brazil-Medico* for December 28 is devoted to obituary notices and appreciations of the recently deceased professor of clinical medicine in the University of Rio de Janeiro. He was born in 1871. When but 23, and still a medical student, he was one of a commission to investigate an outbreak of cholera morbus in the Parahyba Valley. He did not graduate in medicine until 1897. He filled several minor chairs until 1910 when he became professor of clinical medicine. During 1909-1910 he studied in various European capitals. Knowing himself in the grip of a fatal malady he continued his activities and worked upon his forthcoming treatise on the practice of medicine. Death overtook him in the midst of his labors from asphyxia consequent upon the escape of pus from a great cavity in the lung. He had a military record, having taken part in the warfare of the army revolt in 1893 and was also prominent in civics. Both the Senate and House of Deputies honored his memory in special exercises.

Oil of Chenopodium.—In a recent study of chenopodium and its volatile oil, made by Mr. Elmer H. Wirth of Sandusky, Ohio, the holder of the Frederick Stearns & Company fellowship in pharmaceutical research at the College of Pharmacy, University of Michigan, some interesting facts were brought to light regarding the plant itself, as well as the presence of the oil in the fruits and leaves. Perhaps the most interesting is the pharmacognosy of the fruit. Some of the authors on the subject seem to believe that the oil is contained in the seed itself. Mr. Wirth's investigations have shown that this is not the case. but that the oil is present only in the glandular hairs attached to the exterior of the pericarp. Recent pharmacological investigations have brought forth an available method for the determination of anthelmintic properties, which will serve to check results. If sufficient time is available, it is intended to make a study of the relationship between chemical constitution and anthelmintic action.

PNEUMONIA AND EMPYEMA IN THE LATE WINTER OF 1917-1918.

By

EDWIN HENRY SCHORER, Major, M. C., U. S. Army.
F. D. CLARK, Captain, M. C., U. S. Army,
RAYMOND SANDERSON, Captain, M. C., U. S. Army.
JOHN D. DICKSON, First Lieut., M. C., U. S. Army,
FRANK M. HUNTOON, M.D., Contract Surgeon, U. S. Army.

Port of Embarkation, Hoboken, N. J.

THESE studies were made in the laboratories of the Base Hospital at Camp Merritt. The hospital was opened for patients early in January, 1918. It was the receiving hospital for soldiers who became ill just before they were ready for embarkation and because of this we had relatively few soldiers permanently stationed here and had relatively few of the epidemic diseases met with in the training cantonments. The pneumonias and empyemas we had have therefore seldom been associated with measles.

The laboratory has been well established since February 25, but it was not until March 28, that we were organized sufficiently to have a bacteriological study of every case of pneumonia and empyema occurring in the hospital.

This report, purely from the bacteriological laboratory, includes all cases of clinically diagnosed pneumonia and empyema in the hospital from March 28 to May 15, 1918, and such other cases of pneumonia and empyema as were studied from February 25 to March 28, 1918. We will refer to "bronchopneumonia" and "lobar pneumonia" as they were diagnosed clinically. Few cases followed measles, some were associated with diphtheria bacillus infection, some of the cases developed in the hospital and some in the camp but as the stay of troops here was short, most of the cases began in the camp of training or on the way to Camp Merritt. Every effort was made to make the laboratory study as complete as is possible. By hospital orders sputum from every patient as soon as diagnosed clinically as having pneumonia was sent to the laboratory and then without special request the white blood cells were counted on the first and tenth days of the disease. Every fluid withdrawn from the chest was sent to the laboratory for examination and again without request the white blood cells were determined on that day, the first, second, third and tenth days after operation. Throat cultures were taken on all patients admitted to the measles wards. All cultures obtained were studied and a number of patients with measles, pneumonia and empyema received repeated injections of autogenous vaccine made from their respective cultures.

1. *Types of Pneumonia and Empyema as They Occurred at Autopsy.*—The type of pneumonia and empyema prevailing at this hospital probably represents the types found at the various camps, as troops have come here from practically all of the camps.

In analyzing the results of our observations it would be somewhat misleading and of no special value to state figures or give percentages since the material for pathological study was derived from a very small number of necropsies performed at this Base Hospital. In this series of cases we have paid particular attention to the two chief varieties of the disease, namely, lobar and bronchopneumonia.

While there have been many predisposing or contributing factors, the chief exciting causes appear to have been pneumococci and hemolytic streptococci as will be shown more fully later. Other organisms have been present such as nonhemolytic streptococcus, influenza bacillus, and a gram negative bacillus. It is with the *Diplococcus pneumoniæ* and the *Streptococcus hæmolyticus* that we are chiefly concerned, for we believe that the former produces most of the acute lobar pneumonias, such as are seen in civil life, and the later a special variety of "bronchopneumonia" sometimes called interstitial bronchopneumonia. We have also found at necropsy a few cases where a combination of the two types of the disease occurred with a mixed infection of pneumococcus and streptococcus. It is more than likely that one or the other of the diseases was primary, producing its type, followed later by a secondary infection and subsequently developing another variety. The clinical features of these combined pneumonias seem to bear out this contention, and probably this is the only means whereby an early diagnosis as to which variety was primary can be determined.

In considering the pathology of lobar pneumonia, certain fundamental facts should be kept in mind: First, that the infection presents three phases: a phase of incubation with an explosive onset of the disease; a clinical phase in which the anatomical and functional manifestations are most marked, and an immunization phase characterized by the crisis. Each of these phases presents its own pathological phenomena. Second, that the avenue of invasion in the majority of cases is hematogenic and that the inflammation makes its beginning by a perivascular round cell infiltration in the interalveolar septa with exudation into the alveoli. Third, that one or more

lobes are uniformly and simultaneously involved in a process that is more or less self limited. There are also good reasons for regarding these changes that lead to lobar consolidation as local defensive reactions. As stated above the most marked anatomical changes and functional disturbances are presented during the clinical phase of this infection. The well-known anatomical picture recognized by pathologists since the days of Laennec still holds. The inflamed lung presents the stages of engorgement, red hepatization, gray hepatization and resolution. The more minute description of the histological changes of these stages is so familiar to all that there is no need for repetition or further elaboration.

The lobular type of the disease from a pathological standpoint divides itself into three groups of cases. (1) Those with a marked bronchitis and bronchiolitis with very little consolidation. Microscopic examination will show the alveolar passages and a few contiguous air cells filled with the products of inflammation. This is sometimes called capillary bronchitis. (2) This is by far the most common and presents a disseminated bronchopneumonia. There are scattered areas of peribronchial hepatization with patches of collapse of lung tissues. Much of the lobe is still crepitant. When this type is produced by an overwhelming infection with a virulent organism there is more marked interstitial change with hemorrhagic foci scattered throughout the lung. This has been called "interstitial bronchopneumonia," a term seemingly better expressing the more salient features of the lesion. (3) The pseudolobar form. Here we find the greatest part of the lobe is consolidated, though not uniformly. There are intervening areas or strands of congested lung tissue between the hepatized lobules.

The microscopical picture in a lobular pneumonia is quite different from that of a lobar pneumonia. The exudate is less fibrinous and not as a rule hemorrhagic. It consists of mucus, leucocytes, and swollen epithelium. The walls of the bronchi are swollen and present marked round cell infiltration. The avenue of infection is bronchiogenic, the inflammation begins in the tubes and works downward and outward, the continuous and contiguous alveoli next to the bronchi are densely filled.

Macroscopically, in the frequently occurring interstitial or organizing bronchopneumonia the lung presents in the early stages a smooth and glistening pleural surface. It is also found to contain considerable air while at the same time may be noted the beginning formation of patches of atelectasis. Small nodular masses may be felt throughout the lungs. On section the surface is studded with gray peribronchial nodules which protrude. These nodules are surrounded by a red or grayish halo, and have been many times mistaken for miliary tubercles. On close inspection the lumen of the bronchiole may be seen as a crater-like opening or it may be filled with an opaque material. The exudate in this stage is like that in the earlier stage showing very little fibrin, but with detached and disintegrated bronchial epithelium. The walls are hyperemic and much thickened, due to the process of infiltration. Large numbers of mononuclear cells have seemed to replace many leucocytes that were found in the earlier stage of the disease. The exudate in the contiguous and continuous alveoli appears less hemorrhagic. The interlobular septa are markedly thickened and stand out very prominently as grayish yellow lines. Empyema was present in all our cases of bronchopneumonia that came to autopsy. In all these cases the *Streptococcus hæmolyticus* was demonstrated. In the early stages the exudate was thin, turbid and greenish in color, containing shreds of fibrin, and a thin fibrinous coating covered the lungs' surface. This in the early cases could be easily wiped off, but later by reason of organization it became very adherent. In many of our cases there was a very large amount of fluid accumulated, both between the parietal and visceral pleuræ, and between the lobes of the lungs themselves, giving rise to what at times appeared as lung abscesses.

II. *Results of Pneumonia Sputum Examinations.*—From February 22, 1918, to May 15, 1918, there were made 219 examinations of sputum for type of pneumococcus and the presence of hemolytic and non-hemolytic streptococci. At times other organisms, especially *Bacterium influenzæ*, were noted on the records, but inasmuch as the other organisms found were not noted carefully, reports on these are excluded from this report.

Technique of Sputum Examination for Type Determination: Specimens from deep down in the lungs were requested sent to the laboratory in wide-mouth sterile bottles as soon as the diagnosis of pneumonia was made. Care in obtaining a proper specimen is of prime importance. A lump of the sputum was washed in three changes of salt solution and ground with sterile sand in a small mortar. After mixing with a small amount of salt solution one half of a blood agar plate was stroked and a smear for Gram stain made. From 1 to 2 c.c. of this emulsified sputum was placed in dextrose (6 per cent.) blood (5 per cent. defibrinated) broth tubes and incubated at 37° C. for five hours or longer according to the degree of growth produced. When specimens came in too late to be finished the same night a small amount of calcium carbonate was added to the dextrose blood broth as a "buffer" and the incubation continued until the next morning. This was found to work very satisfactorily. The high percentage of dextrose was used on account of the dilution of the media by the large amount of sputum emulsion necessary in poorly obtained specimens.

When sufficient growth was obtained in the dextrose blood a culture was made on the other half of the blood plate and a smear taken for the Gram stain. The upper part of the tube was pipetted into another tube, centrifuged at low speed to throw down the débris, after which bile solubility was tested. Bacto-Oxgall (10 per cent.) was used in testing for bile solubility. The bile treated suspension was then centrifuged at high speed until a perfectly clear fluid was obtained for the precipitin tests. The usual technique and dilution were used. Capillary droppers were used in measuring diluted serum and fluid to conserve serum. The pipettes were washed in sterile water between use in different fluids.

On the clinical records the 219 specimens of sputum examined were classified as being from the following types: lobar pneumonia, 151 cases; bronchopneumonia, 28 cases; combined lobar and bronchopneumonia, 2 cases; not pneumonia, 38 cases. This leaves 181 cases of clinical pneumonia to be considered. The results of the sputum examined are shown in Table I.

Table I.—Showing Type of Pneumonia, Bacteriological Findings on Examination of Sputum, and Final Results of Cases.

Bacteriological Findings.	Clinical Diagnosis.				Disposition of Pneumonias.			
	Lobar.	Broncho.	Both Lobar and Broncho.	Not Pneu	Well.	Died.	Remaining.	Total.
Type I alone	8	0	0	2	5	2	1	8
Type I and hem. strept	15	2	0	0	7	4	6	17
Type I and non-hem. strept	6	0	0	0	2	0	4	6
Type II alone	3	1	0	0	1	1	2	4
Type II and hem. strept	6	0	0	0	3	2	1	6
Type II and non-hem. strept	5	0	0	1	1	1	3	5
Type III alone	6	0	0	1	4	2	0	6
Type III and hem. strept	6	3	0	1	3	4	2	9
Type III and non-hem. strept	3	0	0	0	0	1	2	3
Type IV alone	6	1	0	4	2	2	3	7
Type IV and hem. strept	14	3	2	5	6	4	9	19
Type IV and non-hem. strept	10	1	0	1	5	1	5	11
Not type or strept	12	1	0	1	7	2	4	13
Hem. strept. alone	31	12	0	16	15	12	16	43
Non-hem. strept. alone	20	4	0	6	8	4	12	24
Totals	151	28	2	38	69	42	70	181

From the table it will be seen that of the 181 pneumonia cases 101, or 55 per cent., showed one of the four types of pneumococci as follows: Type I, 31 cases; Type II, 15 cases; Type III, 18 cases; Type IV, 37 cases. Of the sputa in which type pneumococci were demonstrated only 25, or approximately 25 per cent, contained pneumococci alone, as follows: Type I, 8 cases; Type II, 4 cases; Type III, 6 cases; Type IV, 7 cases, and approximately 75 per cent. of the sputa contained type pneumococci and hemolytic or non-hemolytic streptococci. Of the 181 clinical cases of pneumonia 13.81 per cent. were pure pneumococcus, 94 cases or 51.93 per cent. showed hemolytic streptococci alone or in combination with type pneumococci, 43 cases or 23.7 per cent. hemolytic streptococci alone, 49 cases or 27.07 per cent. non-hemolytic streptococci alone or in combination with type pneumococci, 24 cases or 13.2 per cent. non-hemolytic streptococci alone, and 13 cases or 7.18 per cent. showed neither type pneumococci nor streptococci.

Of the 38 "not pneumonia" cases from which sputum was examined fifteen showed precipitin reactions with fixed pneumococcus type sera; two of Type I alone, one of Type III alone, and four Type IV alone, while one showed Type II and non-hemolytic streptococci, one Type III and hemolytic streptococci, five Type IV and hemolytic streptococci and four Type IV and non-hemolytic streptococci. In the sputum of one, neither type pneumomocci nor streptococci were found, while in 16 only hemolytic streptococci were found.

The results obtained from sputum examination are not very different from those obtained at the laboratories at the Base Hospital, Fort Riley, Kansas, where many of the cases of pneumonia and empyema followed measles.

Clinical Result of Clinical Pneumonias from which Sputum was Examined (181 cases): Of these 181 cases 42 died, 69 were sent to their Regimental Infirmaries or were transferred to other Port of Embarkation Hospitals presumably cured, and on May 15 there were still in the Base Hospital 70 of these cases. (The empyema complications will be considered in another portion of this report.)

Of the 42 deaths, 7 were in cases of "pure" pneumococcus cases (17.39 per cent.), 16 were cases complicated with hemolytic streptococci (23.18 per cent.), 34 were cases complicated with non-hemolytic streptococci (49.27 per cent.), and 7 cases showed neither pneumococci nor streptococci (10.14 per cent.).

III. *Empyema.*—Empyema has been the most frequent and important complication of pneumonia. As has been indicated above, purulent fluid was found free and encapsulated between the parietal and visceral pleura, between the lobes, in the pericardium, the peritoneum, the mediastinum and between the layers of fascia.

During the time of our investigation there are known to the laboratory to have occurred 81 cases of empyema. These were recognized from the examination of the exudate obtained at the aspiration, the operation or at the autopsy.

Operations were done on 7 patients the fluids of which were not sent to the laboratory.

Sterile chest fluids were sent in from 25 patients. Cultures obtained were studied from the fluids of 66 patients. From 56 or 84.8 per cent. of these fluids hemolytic streptococci alone were obtained, pneumococci Type I were obtained three times, Type II two times, Type IV four times and Type IV and hemolytic streptococci together one time. The disposition and results obtained as far as the cases in which the laboratory played a part are indicated in Table II.

Table II.—Table Showing Laboratory Findings in Empyema, Disposition and Results.

	Operated on.			Not Operated on.		
	No.	No. Died.	Per Cent Died.	No.	No. Died.	Per Cent Died.
No fluid examined	7	2	28.6	0	0	.....

Pneumococci and hem. strept	1	1	100.0	0	0	.....
Sterile	2	0	0 0	25	0	0.0

*One patient was tapped repeatedly, he still had purulent fluid in the chest when transferred from this hospital.

Results of Sputum Examinations in Relation to Empyema: According to hospital orders sputum was to be sent to the laboratory as soon as pneumonia was diagnosed. What really happened is shown in Table III.

It will be observed that sputum was sent to the laboratory from less than 60 per cent. of the patients having pleural fluids. Undoubtedly sputum was not sent from all patients diagnosed as having pneumonia, and undoubtedly not all

pneumonias were diagnosed, but it seems probable that pleural exudate and empyema often occurred as early as it was possible to diagnose pneumonia. The autopsy on one patient showed marked empyema over quite normal lung.

TABLE III.—SHOWING MATERIALS AVAILABLE FOR LABORATORY EXAMINATIONS IN DIAGNOSED CASES OF PNEUMONIAS AND EMPYEMA.

		Sputum Sent to Laboratory.		Sputum Not Sent to Laboratory.	
Total fluids in chest	106	61	57.5%	45	42.5%
Empyemas	81	46	56.8%	35	43.2%
No chest fluid sent	8	0	0.0%	8	100.0%
Sterile fluid	25	13	52.0%	12	48.0%
Empyema fluids examined	66	46	69.6%	20	31.4%

The type of chest fluid developed after pneumonia as it corresponds to the organisms causing the pneumonia, determined by examination of the sputum, is shown in Table IV.

TABLE IV.—SHOWING RELATION OF SPUTUM FINDINGS TO CHEST FLUID FINDINGS.

Total	106	57	9	25	7	7

From the table it will be seen that the empyema complicating type pneumococcus pneumonia was more frequently caused by hemolytic streptococci than by pneumococci. In four cases the empyema was caused by type pneumococci when no pneumococci were found in the sputum. Of 22 cases of pneumonia in the sputum of which no pneumococci but hemolytic streptococci were found, three had empyema caused by type pneumococci. In all but four of the empyemas complicating pneumonia, in the sputum of which hemolytic streptococci alone or together with type pneumococci were found, the empyema was caused by hemolytic streptococci. Of the chest fluids obtained from cases of hemolytic streptococcus pneumonia seven or nearly one-third were sterile. The frequency with which the various pneumonias caused chest fluid and empyema is shown in the next table.

Table V shows the frequency of occurrence of chest fluid with the various bacteriological observations of the sputa examined. From the table it will be seen that type pneumococcus pneumonia was complicated by fluid in 35.5 per cent. of the cases; hemolytic streptococcus pneumonia in 37.2 per cent of the cases; hemolytic streptococcus and type pneumococcus pneumonia in 26.8 per cent. of the cases; non-hemolytic streptococcus pneumonia in 16.6 per cent. of the cases and mixed non-hemolytic streptococcus and type pneumococcus pneumonia in 13.8 per cent. of the cases. Twenty-five of the pleural fluids were sterile, 28 per cent. of these complicated hemolytic streptococcus pneumonia.

IV. *Strains of Hemolytic Streptococci.*—A critical study of the hemolytic streptococci was made. In all we had 85 separate isolations of which 40 were from pleural fluids drawn during life, 26 were from pneumonic sputa, 7 from tonsil swabbings of measles patients, 6 obtained at autopsy, and 2 from blood cultures and 4 from other sources. We attempted to differentiate these on appearance and size of colonies; amount and rapidity of hemolysis of human blood, both on plates and in liquid medium; microscopic appearance; length of chains; presence or absence of the capsule; bile solubility; fermentation of sugars; and production of immune substances.

On most of these lines of study we could get no differentiation; but by hemolysis, presence or absence of the capsule, bile solubility and fermentation of the sugars we were able to differentiate certain definite types. In some instances we obtained separate isolations of hemolytic streptococci from the same case. All findings were verified at least once and in many instances a number of times. Fermentation tests were made in peptone water with 1 per cent. of the sugar, using Andradi indicator. The reaction was read in 24 and 48 hours. Our findings are indicated in the tables on page 677.

It will be noted that the amount of hemolysis varied some and that some of the streptococci isolated from empyema cases had a capsule and were bile soluble. On the basis of fermentation of sugars there are four main groups of hemolytic streptococci.

On analysis of Table VII it is found that of the different strains of hemolytic streptococci, Group A occurred most frequently and is therefore called the main group. The statistics are shown in Table VIII.

For immunizing purposes strains were selected from each of the several groups; strain SH5 from the group, which for present purposes may be called the main group, represented by far the largest number of strains tested (in this group fermentation is confined to dextrose, lactose, saccharose, and salicin); SH13 from a group of 3 strains which, in addition to the above, fermented raffinose; SH76 from a group of 4 strains which differed from the main group in fermenting mannite; SH88 which in addition to the four main sugars fermented inulin, but which in growth characteristics and hemolysis was a streptococcus; and finally SH90 which differs from the main group only in weak and slow fermentation of lactose.

These strains were grown for 24 hours on hor-

mone broth plus 0.1 per cent. dextrose, centrifuged and the sediments made up with salt solution to a moderately dense suspension. This was heated to 60° C. for 30 minutes and immunization started by injections of ¼ c.c. of suspension intravenously into five large white rabbits. The normal weight of the rabbits was determined by several days of weighing, the condition of the rabbits after immunization had been started was determined by the same procedure. The strains of streptococcus had been grown on artificial media for 30-60 days before immunization was begun. As no reaction, loss of weight or appetite was evident from the first dose, the dose was increased to ½ c.c. on the second day and 1 c.c. on the third day. (The rabbit injected with SH76 died suddenly during the night and autopsy revealed no demonstrable cause of death.) After this living cultures were injected, the suspension increased until syrupy in consistence. At no time was any reaction apparent nor did the animals show any distress, loss of appetite or decrease in weight. At one period in the course of immunization in the hope of increasing the precipitin factor, one series of injections with organisms which had been digested in NaCl solution at incubator temperature for 48 hours was employed. At first the attempt was made to determine the agglutinin content of rabbits' sera; however, owing to limitations of equipment in the field laboratory, it was impossible to obtain such stable suspensions as are necessary to show definitely the end points of this reaction. Evidence was forthcoming of a definite agglutinin content which was apparently about equal for all strains of different groups employed. The technical difficulty encountered prevented the use of the absorption test which would have given definite evidence of specificity of each serum. Preliminary work having shown that many of the strains employed were more or less bile soluble, it was thought that it might be possible to employ the precipitin reaction as a measure of the immunity produced. These strains had shown themselves to be most soluble when tested with a 10 per cent. solution of dried ox bile, but this bile when tested against serum of patients suffering from streptococcus infection had shown precipitation even in very high dilutions and at that time was discarded as probably introducing a source of error. As fresh ox bile when tested with rabbits' serum showed no evidence of precipitation, this was employed in the precipitinogen preparation.

The precipitinogen antigen was prepared by dissolving the washed sediment of bacteria in normal salt solution to which ¼ volume of bile was added. This was then heated to 55° to 60° C. for fifteen minutes in a water bath, then centrifuged and the supernatant fluid used in the antigen. Tests against antigen prepared in this manner showed that the animal receiving SH5 was producing by far the strongest serum, and that serum from this animal caused distinct precipitation in a dilution of 1 to 10 and in some cases 1 to 20 of all five of the tested strains. The precipitation was less in SH13 than in the others employed. The results indicated led to one of two conclusions: either the strains employed are serologically identical, or the so-called group factors have completely overshadowed the specific antibody. In an endeavor to produce antigen containing either only group or specific antibody, various methods of extracting the organisms were employed.

Second method of preparing antigen. To the centrifuged organisms was added 1 c.c. of concentrated salt solution. This was then placed in a water bath for 24 hours, then diluted with 5 c.c. of water, rendering the solution twice normal. This antigen was then tested against serum which had been so diluted with water that the final test was in practically a normal salt solution. The results obtained by this method were practically identical with those obtained with the bile method.

A third method employed was to add to a strong emulsion of the organisms about 15 per cent. of antiformin, then to heat in the water bath at 60° C. for 15 minutes, at which time the solution cleared up to a marked extent. Phenolphthalein and 10 per cent. HCL were then added drop by drop with vigorous shaking until all the color had disappeared. After centrifugation the supernatant fluid was employed for precipitin tests. The results were similar to those obtained with the antigen prepared according to the first two methods.

Fourth method. The supernatant fluid obtained from methods 2 and 3 was precipitated by the addition of about 20 volumes of 95 per cent. alcohol, the resulting flocculent precipitate collected by centrifuging and redissolved in a small amount of physiological salt solution. When tested it gave results similar to those obtained with the other antigens, with the exception that antigen so prepared showed lower titer for all strains.

Fifth method. The residue left after treatment with concentrated salt solution (method two) was dissolved in antiformin as above and tested without results.

It was evident that by the means employed no differentiations could be made serologically between the strains, although particularly in the case of SH13 and SH88 marked constant differences in growth and ease of solubility prevailed over considerable periods of time when all the growths were kept on the same media. The serum obtained from a rabbit immune to SH13 remained of comparatively low titre, whereas that produced from SH88 showed as high titre as that produced by SH5. The precipitin reaction measured by a definite amount of precipitate occurring in 24 hours was positive at times in as high a dilution as 1 to 80, but usually did not occur in dilutions beyond 1 to 20 or 1 to 40.

In an endeavor to separate the specific and the group factors in immune sera a resort was made to a homologue of the absorption test with agglutinins. Preparations as for precipitin were set up in dilutions of 1 to 2 or 1 to 2½ incubated at 37° C. for two hours and then placed over night in the ice box. These were centrifuged and the supernatant fluid retested for the precipitin content. Such tests showed that when absorption had taken place with heterologous strains, the reduction of the titre, for the homologous strains was from 1 to 40 to 1 to 10. Absorption with the homologous strain showed a still further reduction of the titre for all strains tested, *i.e.* there was an apparent specific factor which reacted in a dilution of 1 to 10, and which under the ordinary conditions of testing was completely obscured in

high dilution in the presence of an excessive number of so-called groups or minor antibodies. Cross-tests with various sera and organisms gave rather uniform results in this particular. However, the comparatively low titre of the sera which is usual in bacterial precipitin reactions and the rather large amount of serum that would be necessary in order to do any extensive series, precluded the idea of using all the strains available from the different groups. The evidence so far obtained by this experiment may be summed up as follows:

1. It is entirely possible to produce sera against hemolytic streptococci giving as high precipitin titre as is usually the case with animals immunized against the pneumococci. This may or may not be useful in connection with a diagnosis of streptococcus infections.

2. The portion of the hemolytic streptococci which furnishes the precipitin factor is certainly soluble in bile, and thus forms an easy and rapid method of producing such antigen.

3. The absorption test, while not conclusive as yet, points to the view that these strains which show a different biological activity as far as the fermentation reactions go, have a very large common group factor, but also contain a definite specific factor which establishes them as a separate entity.

V. *Active Immunization or Vaccination with Autogenous Vaccines of Hemolytic Streptococci.*—Active immunization to hemolytic streptococci was attempted in 24 patients with empyema and 19 patients with pneumonia caused by hemolytic streptococci, and with 7 measles patients from whose throats hemolytic streptococci had been isolated. In the preparation of vaccine only hemolytic streptococci were used. As soon as a culture of hemolytic streptococci was obtained from the sputum, chest fluid or from the tonsils, it was transplanted on slant harmone agar and after 24 hours the growth was washed off with sterile salt solution. The suspension was finely divided by shaking with sterile sand, centrifuged slowly, then the number of cocci was counted by the Wright method, diluted properly so as to make a suspension containing 500 million cocci per cubic centimeter, sufficient cresol was added to make a 0.25 per cent. solution. The vaccine was heated for an hour at 60° C. and tested for sterility in the final container. In this way autogenous hemolytic streptococcus vaccine was made for patients injected.

The dosage, method of injection and interval between injections varied in the different cases. In empyema the first injection consisted of from 10 to 50 million cocci, given intravenously. On the next day from 50 to 250 million cocci were injected intravenously. On the third day from 250 to 500 million cocci were given subcutaneously, on the fifth and sixth days from 250 to 750 million cocci were given subcutaneously, and on the eleventh day 100 to 500 million were given intravenously. Very seldom was either local or general reaction produced, except a rise of one to two degrees of temperature. In pneumonia and measles about the same dosages and intervals were adopted but usually only subcutaneous injections were made. The statistical results of attempts at active immunization in empyema due to hemolytic streptococci are shown in Table IX.

It will be noted while active immunization in empyemas was being tried, (1) that the death rate for the total series of empyema was 46.8 per cent., (2) that for those of the series not vaccinated the death rate was 52 per cent., (3) while for those actively immunized the death rate was only 37.5 per cent. It will also be noted that the hemolytic streptococcus empyemata in which only type pneumococci were found in the sputum did better than when hemolytic streptococci or type pneumococci and hemolytic streptococci were found in the sputum. This must evidently be due to group

antibodies and indicates that pneumococci produce more immune bodies than do hemolytic streptococci.

The beneficial results of vaccination impressed themselves markedly, as every empyema patient vaccinated was extremely ill and in some cases it seemed useless to even try active immunization. Gradually these patients improved and a large percentage are apparently well. Until contrary evidence is introduced it seems as though it is advisable to add active immunization to the other means of treating hemolytic streptococcus empyema.

In the pneumonia series, 19 patients with hemolytic streptococci in the sputum were immunized with the hemolytic streptococcus from the sputum and 9 or 47 per cent. developed empyema against 25 per cent. in our whole series. Of actively immunized pneumonia patients developing empyema 3 or 33 1/3 per cent. died, against 43 per cent. in the whole series of corresponding cases of empyema operated on, and 45 per cent. of the same cases not receiving active immunization. This further emphasizes the value of active immunization with hemolytic streptococcus vaccine.

Seven measles patients received injections of vaccine made from hemolytic streptococci isolated from their own throats. Of these only one developed empyema and he died. Since our series a number of measles patients have been admitted to the hospital and in the throats of some hemolytic streptococci have been found and still they have not developed pneumonia or empyema, so that no conclusions showing the value of hemolytic streptococcus vaccine in measles can be claimed for our series.

VI. *Leucocyte Counting.*—It is the usual custom in the hospitals in the Port of Embarkation to send to the laboratory sputum from all patients diagnosed clinically as having pneumonia. The laboratory then does a white blood count on that day and again on the tenth day. While there was marked variation in the initial leucocyte counts, still generally in the actual cases of pneumonia the white cell count varied from 8,000 to 25,000. After ten days in uncomplicated cases the leucocyte count was usually down to 10,000 or less. There were a few cases in which there was no increase in the leucocyte count on the first days of the disease—these terminated unfavorably.

All fluids withdrawn from the chest are sent to the laboratory and white blood counts done on the first, second, third and tenth days following. In all of our empyemas there was an increase in leucocyte count. The ten-day count on the pneumonias was of value in detecting some of the empyemas, and after operation if the leucocyte count did not go down, or if it again came up on the third or tenth days, some foci had not been located and drained or new ones were being formed. The leucocyte counts were not constant for the various pneumococcus and streptococcus types either in pneumonia or empyema.

Conclusions.—1. Pneumonia of three types—lobar, broncho-, and combinations of the two were observed. Many of the cases were what MacCallum, Cole, and their coworkers have called interstitial bronchopneumonia, but of these very few followed measles or other contagious diseases.

2. Empyema was the most frequent and serious complication. Of 181 pneumonia patients whose sputum was examined 81 had fluid in the chest, and of these 56 had a purulent pleural exudate.

3. Hemolytic streptococci were found in 51.9 per cent. of the pneumococcus sputa, 53.7 per cent of the pleural exudates and 70.4 per cent of the purulent pleural fluids.

4. Thirty-four per cent. of straight pneumococcus pneumonias were complicated by chest fluid and 25 per cent. by empyema; 26.3 per cent. of pneumococcus and hemolytic streptococcus pneumonias were complicated by chest fluid and 24.9 per cent. by empyema; 15 per cent. of pneumococcus and nonhemolytic streptococcus pneumonias were associated with pleural fluid and 7.5 per cent. with empyema; 26 per cent. of all pneumonias in which pneumococci played a part had chest fluid and 20 per cent. had empyema. Hemolytic streptococcus pneumonia was complicated in 37.3 per cent. of the cases by chest fluid and in 25.4 per cent. by empyema. In spite of the fact that in the 116 cases of pneumonia in which we found type pneumococci, 22 of the 26 empyemas were caused by hemolytic streptococci. Three empyemas caused by pneumococci were found in patients in whose sputum we had found no pneumococci. It is our general belief that the hemolytic streptococci are seldom the primary cause of pneumonia, but that usually they assume an important and principal part in the final result of the cases of pneumonia.

5. Some of the hemolytic streptococci or at least a portion of the organisms are bile soluble, this factor being precipitinogenic. According to ability to ferment different sugars, the hemolytic streptococci causing empyema may be divided in four groups. If these groups be accepted we have further argument for the belief that the streptococci are not the primary cause of the pneumonia, but are secondary invaders. These streptococci have a large common group factor in producing precipitin, but also contain specific precipitinogenic groups.

6. In the treatment of hemolytic streptococcus empyema drainage is necessary, the time for this being determined by the condition of the patient. Active immunization by the injection of autogenous vaccine seems to be of value in some cases.

7. In many hospitals routine leucocyte counting on the first and tenth days of pneumonia and on the first, second, third, and tenth days after operation for empyema has proven to be of value. This does not preclude leucocyte counting at other times if indicated.

INFLUENZA ABOARD A MAN-OF-WAR: A CLINICAL SUMMARY

By FORREST MARTIN HARRISON, M.D.,
LIEUTENANT COMMANDER, M.C., U. S. NAVY.

THE pandemic disease which has always been characterized epidemiologically by an extraordinary rapidity of extension and by the large number of people attacked, and clinically by a special tendency to involve the respiratory mucous membranes, generally setting up a tracheobronchitis, has been spoken of under a number of different terms. The early British authors of the seven-

teenth century refer to it as "ague." It would be interesting perhaps to note here that in 1658 Oliver Cromwell died from this affection, when Morton says the country was "one vast hospital." Since then of course "ague" has come to have a somewhat different meaning. About 1712 the French term "la grippe" came into general use and has been periodically revived on various occasions ever since. Osler recognizes this as the one and only synonym of the disease. The Italian word influenza which means literally, "influence," as if from the atmosphere, first came to England in association with the epidemic of 1743. This derivation and translation would seem to indicate clearly that the peculiarly subtle nature of the outbreaks of this disease was recognized long before the bacteriologic era. At any rate this is the universally accepted scientific name of the disease.

The expression "Spanish" influenza is no doubt a result of a craze for weird nomenclature accompanying war conditions, and probably originated because of the fact that several epidemics had their beginning and spent their force in Spain. This fact, however, should not cause any greater importance to be attached to it, nor arouse any greater fear than influenza without the new name. It should at once be discarded as being very confusing and misleading and whenever the disease in question is referred to it should be spoken of as epidemic influenza.

The history of epidemics of influenza does not differ very materially from that of other diseases spread by human intercourse that are usually called contagious. A widespread epidemic follows the introduction of a specially virulent virus and there is established a general immunity among those of the population who have been infected. As the epidemic dies out, the infection decreases in virulence and only sporadic cases occur. From such cases and probably from chronic carriers, local outbreaks occur; but the general immunity prevents any general epidemic. After a period of years a new susceptible population has replaced the immune one, and with the introduction of a fresh virulent virus a general epidemic is again brought about. This would account for the great susceptibility of young persons, and as it is twenty-eight years since the last great epidemic, we should not expect many individuals above thirty years of age to be now affected.

Hippocrates and Livius refer to an epidemic even as far back as 412 B. C., which is regarded by many investigators as being influenza. Of course, this is more or less problematical, but at any rate the symptoms as recorded by these "fathers" of medicine are identical in every way with the present clinical manifestations of the disease. There then followed a long period of medical history in which influenza was apparently not reported. It must be remembered, however, that during these early times the disease was perhaps confused and combined with other epidemic disorders, and so did not stand out as a distinct entity until a relatively modern period.

The next authentic mention of a serious outbreak was in the 12th and 13th centuries, when several occurred. Then followed four in the 14th, five in the 15th, eight in the 16th, including the pandemics of 1510 and 1580, and eight in the 17th century. Twenty epidemics are recorded in the 18th and fourteen in the 19th centuries, including the pandemics of 1831, 1833, 1837, 1847-48 and 1889-90. In these latter two years the first outbreak occurred in St. Petersburg during October; in Berlin and Paris during November; in Brussels, Copenhagen, London, Vienna, Rome, Madrid, Boston, New York and Philadelphia during December, persisting in each place one or two months. This epidemic fell heavily on Spain, the present ruler, then three years old, being one of the first attacked in Madrid. Following the pandemic of 1890 high incidence of influenza was reported during the winters of 1891-94. There then followed a considerable pause before the disease again appeared in 1907-8 and 1915-16.

America itself has been embraced in several pandemics of influenza. In his remarkable work on epidemic diseases, published in Hartford in 1799, Noah Webster locates the first American epidemic of which he could find an account in 1647. It passed over the whole country and extended to the West Indies.

Benjamin Rush described an epidemic in 1789 in Philadelphia, which was brought there by members of the first Congress which had assembled in New York. Daniel Drake records a widespread epidemic in the West in 1807. These are but isolated cases. As a matter of fact, this country has been seriously affected in all of the big pandemics enumerated above, especially during the 19th century.

During the winter of 1915-16 the United States was visited by a severe epidemic of acute respiratory affections which resembled in every way the great pandemic of 1890. This outbreak was apparently noticed first in the Middle Western States, and it spread rapidly over the entire country, taking a heavy toll of human life. December and January were the months in which the infections were most prevalent, and the epidemic had completely lost its impetus by March.

The present epidemic which is sweeping the country, and which is apparently on the decline now, began in Spain last spring, passing over the whole of Europe, both civilized and barbarian, attacking 30-40 per cent. of the population in Germany, Italy, France, England, and Ireland. It was undoubtedly brought to this country by patients or carriers aboard ship. In the United States the disease has played havoc with the civilian population not only, but with the military forces in the great training camps ashore and afloat. Public Health Service estimates place the number of deaths at not less than 400,000 in this country during September, October, and November, 1918.

The question as to the real nature of the "influence" in influenza has not been definitely settled. Aside from a few observations on previously reported epidemics the most important work on the bacteriology of the disease was done during the great pandemic of 1892. During this year Pfeiffer published his great work in which he described a small Gram negative hemoglobinophilic bacillus as the causative agent, and this gained almost universal acceptance at the time,

except possibly in France. The previously described bacteria, streptococcus, pneumococcus, and staphylococcus, because of their frequent presence in the sputum of normal persons, were henceforth considered as secondary invaders and of minor importance in the etiology of influenza. Recent investigators, however, have failed to corroborate his findings and the Pfeiffer organism has been called into question. Davis and others have repeatedly found these bacilli in various diseases, such as whooping cough, tuberculosis, measles, and chronic bronchitis. Minor epidemics of acute respiratory infection, clinically regarded as epidemics of influenza, have occurred in which the influenza bacillus was not regularly present in the sputum or the respiratory tract. In such epidemics, as well as in the great pandemic of 1889-90, streptococci occurred quite regularly in the respiratory tract. Indeed, a large group of French and German observers regarded the great pandemic as a streptococcus or mixed streptococcus and pneumococcus infection.

As a matter of fact, the only evidence that influenza is caused by the Pfeiffer bacillus up to the time of the present outbreak, is the demonstration by a few men of the presence of this organism among other bacteria in the respiratory tract of patients suffering with influenza. The production of influenza in animals by injections of pure cultures of the bacillus has not given any decisive results. No distinctive immunologic reaction has been discovered showing that the body reacts specifically to the influenza bacillus in the course of influenza. In truth, the evidence in favor of the influenza bacillus is not any stronger or different from that which can be urged in favor of the streptococcus, pneumococcus or other bacteria. And if we grant the possibility that the influenza bacillus may cause outbreaks of influenza, it is diffiicult to determine just wherein lies the deep difference between such strains of the bacillus and strains found in whooping cough, measles, and other conditions.

There is perhaps no disease with the possible exception of dengue which attacks indiscriminately so large a proportion of the population—about 40 per cent. as a rule. As we have stated, the cause is still veiled in mystery. All that we seem to know is that apparently in the course of evolutionary processes there is suddenly liberated a form of infectious agent against which large numbers of people offer little resistance, and which is transmitted from person to person under the most diverse climatic and geographic conditions. During such visitations the general mortality is naturally greatly increased. Why this is so is not definitely known. It may be that the etiologic agent independent of its own virulence increases the death rate by combining with preexisting disease or by lowering the resisting power of the individual to such an extent that other formidable infections gain a foothold and cannot be overcome.

Influenza has always been more or less prevalent aboard the U. S. S. *Salem*, but with the possible exceptions of February, September, and October, 1918, the disease has never assumed epidemic proportions. Fifteen cases occurred during December, 1917, but they were well spread out, and not more than two patients were on the sick list at the same time with the disease. Our records show anywhere from one to six cases being admitted a month over a period of a year or more, with the exceptions mentioned above, a number which can scarcely be considered anything but sporadic. Most of these infections were of the mild type in that the average number of days on the sick list was only 3.35 for each patient. Despite this fact, however, the damage caused by influenza was considerable, and this disease formed a major portion of our illness. With an average complement of 600 men and officers, since the ship was placed in commission in September, 1917, there have been 544 sick days from influenza alone, or a daily average of 2 patients for a period of 13 months.

In studying the cases from time to time I have been particularly impressed by the fact that these sporadic cases as seen in the months other than February, September, and October, 1918, have without exception presented the same symptoms and have run identically the same course as did those cases which occurred when the disease was regarded as being epidemic. From my experience aboard ship I am firmly convinced that the ordinary sporadic case of "la grippe" such as one sees in his daily practice is no different fundamentally from the influenza which we call epidemic. In our series of cases there was no increase in the severity of the symptoms. Neither has the duration been prolonged nor complications been more frequent on account of its presence on board in epidemic form or when associated with widespread prevalence in the civilian community.

Another interesting fact which we could not fail to note was that the climate seemed to exert no influence whatever over the disease. From September, 1917, to September, 1918, we handled 170 cases of influenza. They occurred under the most diverse weather conditions. During 1917-18 the ship passed through a very severe, damp, cold, penetrating winter at the Navy Yard, Boston, Mass., while from April to October, 1918, she was cruising continually in sunny tropical waters under absolutely ideal conditions as far as the weather was concerned. One epidemic occurred in February in Boston, the other in Florida in September. During February and the months previous to it the presence of the disease in epidemic form can be attributed, I believe, to the severe weather and the overcrowding of the ship, which was a necessity of course from a military standpoint. Men were constantly exposed to dampness stood watches in driving rains and snow storms and it is very natural that influenza should flourish under these conditions. The cases which occurred during September and October were a part of the prevailing epidemic. The surprising thing is that the severe weather did not result in any complications, and that all of the complications that did occur took place when the ship was in the South. This was probably due to a virulent strain of the causative organism present in the associated epidemic.

The subjoined clinical summary is based upon observations of 78 cases which came under m

personal care during the very recent epidemic in September and October.

We were able to separate our cases, following the classification given by Osler into four varieties, namely, respiratory, gastrointestinal, nervous, and febrile. By far the great majority were of the respiratory type. As was to be expected the gastrointestinal variety was more or less rare, only 3.83 per cent. of the cases coming under this category. The prominent symptoms were fever, delirium, nausea, vomiting, abdominal pain, diarrhea, and a slight degree of collapse. No jaundice or enlargement of the spleen was noticed. Two of the cases or 2.55 per cent. were of the nervous type. Both of these cases showed no catarrhal symptoms, complained of severe headache, pain in the back and joints, muscular twitching, photophobia, and profound prostration and were ushered in with a prolonged chill. In the three febrile cases fever was the only manifestation, and they would have been undiagnosed, I am sure, if they had not occurred in association with a widespread epidemic.

The incubation period, as nearly as could be determined, was apparently two or three days. Osler states that "the incubation period is from one to four days; oftenest three to four days." There is, of course, no absolute way of telling, as so many factors enter into such a consideration. Laboratory experimentation will alone establish the incubation period.

The onset in a great majority of our cases was sudden, being marked either with a well pronounced chill which lasted, as a rule, from ten to fifteen minutes, or else only chilly sensations alternating with a distinct feeling of warmth. The patient sometimes passed from an apparently well condition almost to prostration within one or two hours. In a few the onset was far more gradual, the man remaining at his work for one or more days before reporting ill. In these cases there was ordinarily a history of lassitude, malaise, indisposition, and slight headache several days prior to the actual attack. Profuse sweating occurred in the majority of cases, which was increased undoubtedly by the medication employed.

This initial chill or period of indisposition was invariably followed by a sudden and sharp rise of temperature, 103.5° F. being an average pyrexia for the first day. In a majority of the cases the fever was highest on admission, in several the greatest rise occurred on the second day of the illness, and in a very few it required the third day to reach its maximum. Our cases from the standpoint of the fever seemed to fall in three distinct classes: mild, with a temperature of 101° F.; moderate, with 103.5° F., and severe, with a fever of 105° F.

The temperature curve in every case showed daily remissions of approximately one degree. Three days was the average duration of the fever; it usually terminated by lysis. In not a few instances the temperature, after falling by lysis or crisis, as the case might be, stayed around 100° F. in the evenings and back to normal in the mornings, the patient in the meanwhile feeling well and fit. This fact was due to an associated bronchitis or pleurisy.

The highest temperature recorded in an uncomplicated cases was 105°F. This was present in only two cases and persisted continually for two days despite energetic antipyretic therapeusis. The most interesting thing about this high degree of fever was the fact that the patients felt comfortable, complained of nothing but a slight headache and drowsiness, and there was no evidence of delirium. The lowest temperature on admission was 99.5° F.

One striking thing in connection with the temperature was that in a great majority of the cases the patients actually felt better with one or two degrees of fever and complained more when their temperatures reached normal. It would seem, therefore, that hyperpyrexia is often a protective mechanism. This fact may have some therapeutic significance.

Rhinitis, with its associated distressing symptoms, such as a sense of fullness between the eyes, sneezing, and a profuse nasal discharge, was noticed in every case, the mucous membranes of the upper respiratory tract being swollen, red, and engorged. Because of this latter fact the patients invariably suffered with a dry hacking cough or hoarseness, a sense of rawness beneath the sternum, or a periodical paroxysm of coughing, at times very irritating. Expectoration was present in a varying degree. The sputum showed nothing characteristic.

Headache was complained of in every case. It varied in intensity, duration, and location, but usually lasted throughout the entire attack. It seemed that the higher the temperature the less the cranial pain. It was described by some as a sharp, lancinating pain; by others as dull and boring, and by a few as only a feeling of discomfort. Sore throat was complained of in only a few cases; the tonsils were rarely swollen, and the cervical or other lymphatic glands were not palpable at any time.

The pulse rate followed the temperature curve in every instance and showed the usual rates. I failed to note a particularly slow pulse as reported by many observers.

Another symptom which was present universally was actual pain and a feeling of soreness in the muscles of the back and over the kidneys and practically all the voluntary muscles and joints. The patient felt as though "he had been beaten all over with a club."

Mental dullness and apathy were common, and in some instances the patient was continually drowsy and slept most of the first 48 hours of his illness. In other cases the headache, backache, or pains in the extremities, together with a general irritability, made the days uncomfortable and the nights restless.

There were various other miscellaneous symptoms recorded, such as epistaxis, earache, and abdominal pain, but these were never very prominent and caused the patient but little distress.

Convalesence did not seem to be marked with any unusual degree of prostration or by exhaustion on slight exertion. As a matter of fact, patients were sent back to duty usually the day after their temperatures had reached normal, and with no ill effects whatsoever.

In our series of cases complications were few. Perhaps the most frequent was an extensive bronchitis and active congestion of the lungs, as evidenced by the presence of piping sibilant râles and the characteristic general symptoms. In one or two cases otitis media occurred, while in others acute myringitis gave the patient a lot of trouble. Pleurisy was seen in three cases.

By far the most serious complication was bronchopneumonia. This occurred, however, in only two of our cases. It was not due to any inability or unwillingness on the part of the patient to stay in bed long enough or thoroughly enough; or to any physiological handicaps, such as organic heart disease or chronic bronchitis or old age. In both cases the symptoms of the complication began on the fourth day and seemed to be due to an extension of an acute bronchitis caused by a particularly virulent strain of the organism, whatever it was.

One of the startling features of the epidemic was its sudden flaring up and its equally sudden decline, reminding one of the flame consuming some high combustible which dies down as soon as the supply of material is exhausted. Within a day or so after its first appearance aboard the ship there is every reason to believe that the infection was universally present in the nose and throat of the entire personnel and disseminated by innumerable carriers. Susceptibility was very general, although varying in degree. There are few among the crew who could not recall having had an occluded or running nose, or a raw feeling in the throat, or a cough, or aches and pains at some time during the prevalence of the disease, these symptoms representing, it seems likely, the price such persons paid for their immunization.

In view of the universal prevalence of the infection quarantine was considered useless and was not even tried. Our cases, however, were all isolated. There are only 14 bunks in our sick quarters, but these were abandoned altogether. A large ward was screened off on the main deck by the use of an awning and canvas and the patients placed on cots, thus insuring plenty of fresh air and sunshine and the maximum net air space and breathing space per man. In other words, the cases were treated practically in the open air and sunshine. We were particularly careful to see that the patients were kept warm by the liberal use of blankets. There is abundant evidence to show that warmth favors the development of immunity and that chilling antagonizes it and causes complications.

In passing, other measures adopted to control the spread of the disease were washing down all compartments daily with a solution of cresol; sterilizing the mess gear by subjecting it to boiling water for fifteen minutes after each meal; flaming scuttle-butt terminals four times daily, and spraying the noses and the throats of the entire crew three times daily with an antiseptic solution. In addition, the men were repeatedly warned of the dangers of and cautioned against promiscuous spitting, coughing, and sneezing.

In the absence of specific treatment the therapy of the disease had to be symptomatic. With the onset of the fever the patient was sent to bed and forced to remain there until a day after his temperature had reached normal. We usually gave a course of calomel in broken doses and followed it up with salts or seidletz powders in six hours. The fever was rarely high enough to be detrimental to the patient. When it exceeded 103° F. antipyretic measures, especially hydrotherapy in the form of ice packs, were resorted to. We used also with a great deal of success cold rectal irrigations.

For the pains and aches to which most of the patients were subject we gave acetylsalicylic acid, phenacetin, and the P. Q. and S. capsule, composed of equal quantities of phenacetin, quinine, and salol. It seemed to be their analgesic action rather than their antipyretic properties that rendered the cold tar derivatives so useful in influenza. Dover's powder was given with a great deal of relief when the patient could not sleep on account of the pain.

For the cough which was invariably present, and especially if there was any retention of secretion and clogging up of the bronchioles, ammonium chloride was resorted to either in capsule, tablet, or some vehicle. The cases sometimes cleared up phenomenally under this drug. The opiates were not added to the cough mixtures except when the chest was free from physical signs and the patient was kept from sleeping by a useless, absolutely non-productive cough. In such cases codeine sulphate, gr. ¼, immediately before retiring or three times daily usually sufficed.

Patients were encouraged to drink plenty of water, and as a matter of fact, some liquid, either in the form of albuminized lemonade or plain water, was given systematically every two hours.

The diet was liquid in every case and was not changed to soft until the temperature had reached normal. The nose and throat were sprayed with argyrol, 10 per cent., three times daily.

It would consume too much space to describe in detail all the other measures that were found useful, such as prolonged irrigations of the auditory meatus with hot water for earache, strapping the lower border of the ribs with adhesive plaster for pain and soreness due to strain from coughing and icebags for headache.

It seems to me that the main point to keep always in sight at the present time is that unfortunately we as yet have no specific treatment serum, or vaccines, for influenza. Such is the fact all claims and propagandist statements in the newspapers and elsewhere to the contrary notwithstanding. This being the case, efforts at treatment and prevention by serums and vaccines now hurriedly undertaken are simply experiment in a new field and the true value of the result cannot be predicted by anyone. Indeed, the exact results can be determined, if at all, only after a time; in most cases probably not until the epidemic is passed and all the returns fully canvassed. As to serum treatment, the only noteworthy new method so far is the injection in severe cases of influenzal pneumonia of the serum of patients who have recovered from such pneumonia. The principle of this method is rational analogous procedures have given seemingly good results in scarlet fever and other diseases, an

the results reported in influenzal pneumonia appear promising. Further trial of this treatment under proper conditions consequently seems to be warranted. Of vaccines we know nothing.

Influenza is a self-limited disease with variable complications and of variable severity in different places, thus offering great difficulties in the way of evaluation of different methods of treatment. The therapy must for the present remain in the main symptomatic, and after all, I believe, this is the very acme of medical art despite the fact that it is often spoken of disdainfully. What a wonderful thing it is to be able to take care of the derangements of the functions of the patient while his system is fighting the infection. It is our duty, not only, but a privilege!

AN ANALYSIS OF TWO HUNDRED AND SIXTEEN INDUSTRIAL ACCIDENTS.

By CARL SCHEFFEL, Ph.B., M.D.,

BOSTON, MASS.

THE following data of two hundred and sixteen industrial accident cases was obtained from the records of a manufacturing plant whose average number of industrial accidents per annum compares favorably with that of other plants in the same line of industry. Only those accidents have been taken into consideration which were of sufficient severity to cause loss of time from work. Males and females are employed in about equal numbers in this industry, their ages ranging from sixteen to sixty years. The average age of those injured is twenty-one and six-tenths years. The plant in which these accidents occurred is well equipped with safety appliances, has good light, and its employees are instructed concerning the hazards

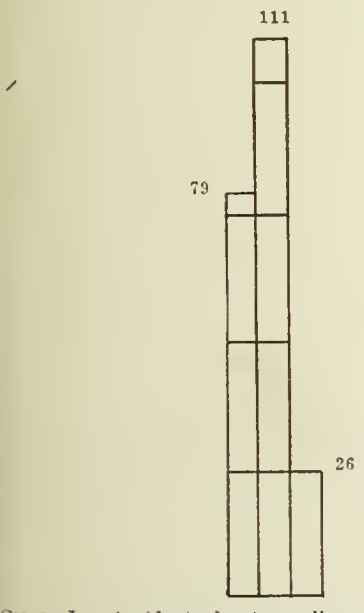

CHART I.— Accidents due to negligence of fellow employees, 26; unavoidable accidents, 79; accidents due to carelessness, 111.

connected with the particular duty each employee is expected to perform.

In the classification of accident causation as shown in chart number one, the term carlessness, as used in this paper, is applied only to those accidents occurring subsequent to some gross violation of reasonable care in their prevention. For instance, where an employee deliberately puts his hands where he has been repeatedly cautioned not to put them; or where an employee cleans a machine while in motion after having been repeatedly warned not to do so; accidents occurring after such acts have been classified as being due to carelessness.

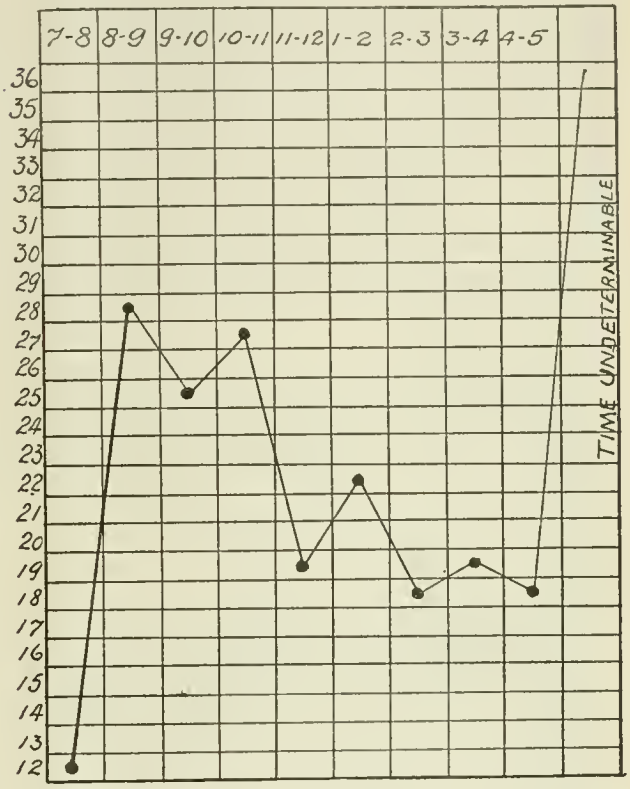

CHART II.—Time of day during which accidents occurred. Those injuries whose time of occurrence cannot be determined are mostly cases of sepsis.

Inasmuch as this plant provides its employees with excellent facilities for the immediate and proper treatment of injuries, and its employees having been instructed to have their injuries—however slight they may appear—promptly treated, cases of sepsis occurring subsequent to refusal or negligence to have primary injuries properly and promptly treated have likewise been classified as being due to carelessness. Those cases of infection which followed prompt and proper treatment have been placed under the category of unavoidable. Accidents where the question of exercising reasonable skill in the performance of some duty is involved are also classified as being unavoidable.

A glance at chart I quickly informs us that by far the largest number of accidents were due to carelessness, even in the limited sense in which the term is used in this paper. One hundred and eleven industrial accidents out of a series of two hundred and sixteen due to gross carelessness is an extremely high percentage and is of sufficient importance to warrant further study with a view to eliminating as many as possible of these unnecessary accidents in the future.

Chart II gives an idea as to the time of day during which these accidents occurred, the plant running from seven-thirty A.M. to twelve-thirty P.M.

and from one-thirty P.M. to five-thirty P.M. The chart shows that in the forenoon the crest of the wave is reached between eight and nine o'clock, gradually diminishing up to noon. In

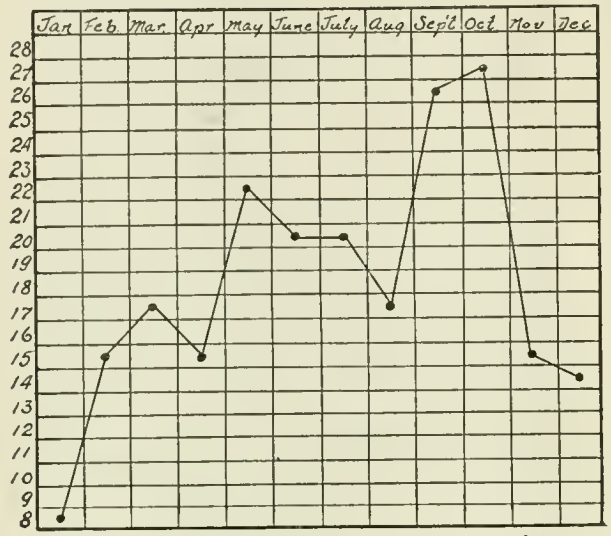

CHART III.—Frequency of accidents by months.

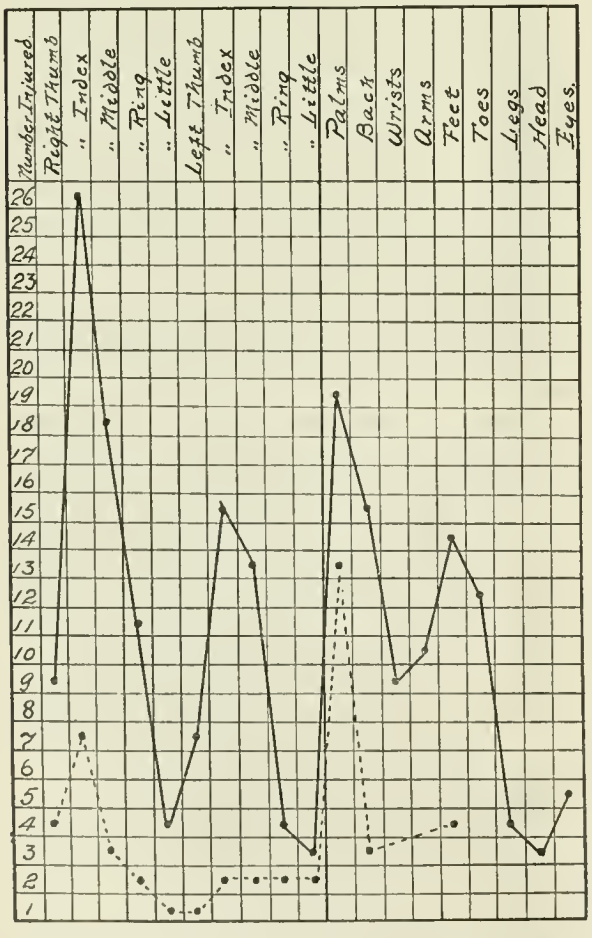

CHART IV.—In numerous instances more than one finger was injured, thus bringing the total number of injuries above 216. The lower broken line represents infection.

the afternoon the largest number of accidents occurred between one and two-thirty. From a study of the wave on this chart it seems logical to conclude that the factor of fatigue does not seriously enter into accident causation at this particular plant, for if it did the height of the wave would have been noted after several hours of continuous uninterrupted work. Or in other words, nearer the noon hour and towards the closing hour when the effects of fatigue would more likely make themselves apparent. The fact, however, that the crest of the wave occurs between the first and second working hours both in the forenoon and afternoon periods, would seem to indicate that the factor of "getting warmed up" to the work after a period of intermission was more important as a factor in accident causation than fatigue itself. Furthermore, if we take this series of industrial accidents incidental to this particular

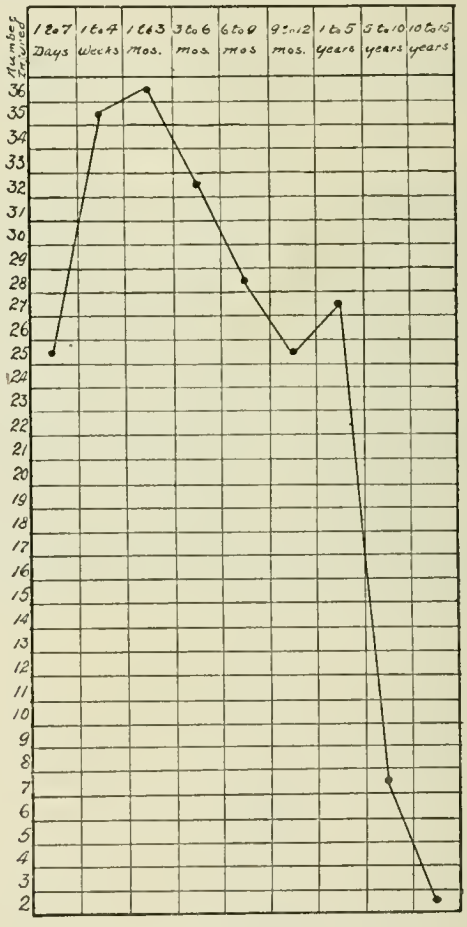

CHART V.—Length of time which those injured had been employed.

plant as a fair average guide, it would seem that the much advocated method of introducing five or ten minute rest periods several times during the day would only tend to increase the accident rate due to the repeated necessity of "warming up" for the work.

Chart III shows the prevalence of accidents by the month. It is rather surprising to note that the height of the curve was reached during the months of September and October. Here again fatigue as a prominent factor in the causation of accidents does not make itself strikingly shown. It would seem more natural to expect the height of the curve to be reached during the hot months of July and August if fatigue played the all important part in

accident causation attributed to it by some authors. Inasmuch as these two hundred and sixteen cases cover a period of three Summers in an industry which is busiest during the Summer months, this curve shows up all the more surprising.

Chart IV enumerates the part of the body on which these injuries occurred, and also the number of infections and the parts of the body which were infected. This line of industry requires almost exclusively the use of the hands and fingers, and as might be expected, these are the members most often injured. Particularly the right index and middle fingers seem to be the victims of the most injury, with the palms of the hands a close third. In this series of accidents palmar injuries seem to be most susceptible to sepsis.

From Chart No. V we learn to confirm a well known industrial fact, namely that a new and inexperienced employee not only costs money to be broken in; but that he is also more likely to be a victim of accident for a varying period of time. This series of industrial accidents would seem to indicate that employees required at least six months' experience in this industry before they ceased to form industrial accident risks above those of the average older employees.

1127 Commonwealth Avenue.

SCOPOLAMINE-MORPHINE IN WAR SURGERY.

By C. W. STROBELL, M.D.,

NEW YORK.

Convinced that an extensive use of scopolamine-morphine anesthesia in military surgery, as applied to our present war, would result in a substantial decrease of suffering, and the saving of large sums of money, I venture to record, very briefly, what I have found of practical value in the method, as applied to surgery in civil life, and presumably, at least equally applicable to the field of battle.

Scopolamine-morphine administered in the field as preparatory to emergency surgery, to be done upon arrival at the dressing station, would be found to be of great value, primarily as an analgesic, and secondarily in anesthetizing the wounded man, en route, so as to have him ready for operation. Such emergency work would comprise the setting and dressing of simple and compound fractures; the reduction of dislocations, the completion of partial shell amputations; the ligation of vessels; trimming and dressing of extensive lacerations, dressing of burns; exploration and extraction of foreign bodies, etc., etc. A first full-strength dose (scopolamine hydrobromide, gr. 1/100, and morphine hydromide, gr. ¼) should be administered hypodermically immediately upon reaching the wounded man. Thirty minutes thereafter a second similar dose should be given in the same way. Thus, at the end of one hour from the administration of the first hypodermic, the patient would be in condition to undergo any of this class of operations. In exceptionally severe cases a trifle of ether may be required.

Major surgical work, allowing of some degree of deliberation, also permits of preparation of the patient for the anesthesia, but of all anesthetics for major operations, scopolamine-morphine requires the least. In other words, the patient does not require any preparation, and least of all, of the gastrointestinal tract. Therefore an initial full strength dose may be given at any time, followed by another, a half hour later. At the end of the hour a half strength tablet is administered, the other half being kept in the syringe in solution, and in readiness, should it be required later. Fifteen minutes after the third injection the operation may be begun. Occasionally a few inhalations of ether may be needed to precipitate the surgical stage. If the operation is very severe or especially prolonged an additional half strength dose of scopolamine-morphine may be necessary. Muscular rigidity or restlessness during the operation is quickly controlled by a breath or two of ether.

Scopolamine-morphine thus administered, with or without adjuncts, confers a surgical sleep that continues for hours after the operation is finished, and from which the patient awakens rested, and normal as regards his ability to take liquid refreshments. It also confers the anociassociation of Crile. In ninety-five per cent. of cases there will be no post-operative sequelæ, such as nausea and vomiting. Therefore the prolonged presence of a nurse at the bedside, immediately following the operation will not be necessary, as the patient may safely be left to "sleep it off."

The occasional moaning and sighing of these patients should not be considered the signal for the administration of anesthetic adjuncts, as these are not signs of distress. Groaning and uneasy shifting about upon the table, however, are indications for the employment of such aid. Light, noise, and rough handling should be excluded. Therefore the ears should be stopped with cotton saturated with zinc oxide ointment. Light should be excluded by cotton and a bandage over the eyes until the surgical stage is reached, when these may be removed. There should also be avoidance of infliction of shocks, as by concussion, rough handling, or hot and cold applications, all of which arouse the patient in a greater or less degree. This surgical narcosis or narcoesthesia can safely be continued for hours, by the occasional administration of a half strength tablet.

Regarding the economic aspect of scopolamine-morphine anesthesia in point of expense, as compared with that of ether, chloroform, nitrous oxide, etc., an actual money saving of 75 per cent. can be effected, with a further 50 per cent. reduction in the time of nurses and attendants. Also there would be a 90 per cent. elimination of oxygen gas from the expense account. As the military bill for these items must be enormous, the above observations would seem worthy of consideration.

For the practical administration of scopolamine-morphine three forms are available: (1) Hypodermic tablet, (2) Standard solution, (3) Ampules. (1) Tablets may be obtained of all pharmaceutical houses. (2) The stock solution is made up much like Majendies solution. (3) Ampules assure asceptic, quickly available con-

tents, and can be used intravenously, hence with more rapid effect.

Hypodermic tablets and stock solutions are best for use on the battlefield. Ampules are best for work in field or base hospitals. Intravenous administration of the drug is as simple as the hypodermic, and absolutely as safe. The time required for this needs not be more than two minutes. As to the technique: It will be sufficient to wipe the bend of the elbow with a weak iodine-alcohol solution, then having an assistant compress the veins of the arm with twist or band (usually the patient can grasp the arm with his opposite hand for the few seconds that it would be needed), select any vein that stands out best, run the needle into the most prominent vein, remove pressure on the arm above, discharge the contents of the syringe quickly, and withdraw the needle. Now another "wipe" of the iodine-alcohol, a temporary compress (not always necessary), and the thing is done.

17 East Thirty-eighth Street.

Medicolegal Notes.

Cause of Optic Atrophy.—A workman, injured in an accident on a logging railroad, claimed under a Workmen's Compensation Act for the loss of the sight of one eye. The physicians called in behalf of the Insurance Department testified positively that the loss of the sight of the applicant's eye could not have resulted from the injury received in the accident; that the applicant was suffering from a primary optic atrophy; that primary atrophy is not due to inflammatory processes, nor is it the result of an injury; that if there had been an atrophy of the optic nerve due to such causes it is called secondary atrophy; that it was likely that the applicant, being afflicted with true or primary optic atrophy, was not aware of his condition, which must have existed for some time before the accident although not discovered until after he had been injured. On the other hand medical experts testifying for the applicant advanced the opinion that there might have been some injury of the optic nerve; that it is almost impossible to make a positive diagnosis in a case like this; that no one can say definitely whether an atrophy of the optic nerve is primary or secondary, without considering the history of the case, and that there is no specific rule to determine positively what has caused the condition. One of the doctors suggested that the learned discourse about primary and secondary atrophy is "dictionary definition pure and simple," and that the term "primary atrophy" is often used for convenience to cover ignorance of the true cause. The court, on appeal from an award of compensation, held that the medical evidence could not be reconciled. The applicant's testimony was that he was a carpenter by trade, that up to the time of the accident he used either eye as convenience dictated, and that there had been no trouble with or diminution of his vision. After the injury the sight of the left eye began to fail rapidly, and at the time of the trial he was practically blind in that eye. A neighbor testified that about a year before the accident he was with the applicant when he was shooting hogs and that he could shoot from one shoulder as well as the other, and that he never complained about his eyesight.

The court said that one of the first inquiries made by oculists in cases of atrophy of the optic nerve is whether the patient has ever been afflicted with lues or any germ-carrying disease. There was no evidence that the applicant was so afflicted. He denied that he was ever the victim of any such condition. It was held that these physical facts, coupled with the opinion of respectable oculists that the condition may have resulted from the accident were enough to sustain the judgment of the court below.—Nelson v. Industrial Ins. Dept., Washington Supreme Court, 176 Pac. 15.

Medical and Surgical Lessons of the War.

THE EDUCATIONAL VALUE OF THE WAR TO THE MEDICAL PROFESSION.*

By Major JOHN A. HARTWELL,
M. C., U. S. Army.
NEW YORK.

In beginning his address the speaker said that though the title assigned to him sounded rather ambitious he would not discuss it from all possible phases but simply from his more or less personal observations and experiences as related to the advances in surgery during the past three or four years. The first obvious advance in medical education that had accrued as a result of the war was that some twenty-five or thirty thousand medical men had been taken into the army and were given the opportunity of receiving intensive instruction in various branches of medicine and surgery. Many had attended formal classes and others had been in active service where they had acquired a much more extensive experience than would have come to them under ordinary circumstances. It was certain that the whole profession had not been able to profit by the experiences of the war as much as might be desired, and the question arose as to what could be done from now on to turn war experience to further advantage. In order to profit by the things the war had brought to the fore, these things would have to be analyzed in relation to our medical schools and post-graduate medical education. Major Hartwell said he did not expect the statement to go unchallenged that there had been no advances in principle in respect to the practice of medicine and surgery brought forth during the war. There was nothing, however, that had come to his attention which he was willing to acknowledge was new in principle in the science or in the art of medicine, but that did not mean that a great deal had not been learned, for surgeons in particular had learned a better application of the things they did know, or should have known, before the war started.

One question was the general one of hygiene and public health. It was well known that this subject in this country had received nothing like the consideration it should have had. We had public health committees in the County Society and the Academy of Medicine—the city, State and Federal Governments had public health organizations, but they were not all that they should be. As a nation we had neglected the general subject of public health and that had acted to a marked degree to the detriment of many people and would still further act to the detriment of many more. Many lay activities had been started to awaken a greater interest in public health problems. The Bureau of Municipal Research had instituted a course of lectures, extending over six weeks, on general hygiene and public health, and an inspection of the list of those giving the course would show that these lectures were being taken seriously. That there was a very broad field for

*Abstract of an Address before the Medical Society of the County of New York, January 22, 1919.

public health work was further attested by the fact that at the Paris Peace Conference the possibility of the formation of an International Board of Health was being considered in connection with the plans for a League of Nations. The importance of the health of the whole world had been brought to the attention of every thinking man through the experiences of the draft boards. Many recruits were thrown out by the draft boards for defects caused by bad hygienic conditions which might have been corrected or prevented, as was demonstrated by the establishment of a training course in this city which resulted in putting a large number of those disqualified for the army on account of defects due to neglect of general hygiene into the service by the simple process of looking after their general welfare, teaching them what to eat, how to eat, and how to take care of themselves. If a man was unfit for military service he was to a corresponding extent unfit for civilian occupation. At the present time few medical colleges had courses on public health. All the teaching the student received on this subject was given in a few lectures, not very carefully thought out and not taken seriously by the students in the medical colleges. In fact very few who finished their course in medical education had any idea of going into public health work. One thing that must be taken up was the establishment of proper courses in public health in every medical school.

On the question of vaccines and serum treatment there had been nothing absolutely new developed by the war, though it was demonstrated that typhoid fever and tetanus could be prevented, and there was much hope held out by the work of Weinberg in Paris and Bull in this country that this might also be done with some other anaerobic infections, such as the gas bacillus. On the other hand, when it came to the treatment of respiratory diseases, the vaccines and sera had not demonstrated their complete efficacy, though there was reason to hope they may do so. Attention must be given to that field of work.

Naturally the speaker's interest was in surgery and in that field he felt that he might venture to speak a little more in detail, as he had been assigned as an instructor in military surgery and had gone to France for the opportunity of gaining a rather complete survey of the treatment and management of war wounds. From one standpoint the experience of the war as it affected medical men might be a little disastrous, in that a large number of men who had had no experience in surgery and before the war no particular desire to practise surgery, on entering the army had been compelled to go into surgical work and under the stress of war conditions had done a great deal of operating; and unless they were very well balanced they might get the idea that they were competent surgeons without realizing that the type of surgery done in France under war conditions was not the type of work that led to good surgery in civil practice, unless the man had been a good surgeon before the war. Such men would need a large amount of help in attempting civilian surgery, and this was a rather important matter.

While it could not be said to be a new principle, unquestionably a most marked success had been obtained in primary suture of contaminated wounds, and this was developed by the British and French surgeons before we were in the war. This method, as was well known, consisted in débridement, that is, removing all tissue in which bacteria could live and multiply rather than in getting rid of all bacteria. After débridement the cases were handled as in a clean primary wound and in about 90 per cent. of these cases, if all the details could be carefully carried out, primary union would take place. This method described by Duval and Tuffier created a great deal of enthusiasm in this country and gave many surgeons the impression that great progress in surgery had been made. It simply meant that the principle we knew had been put into force, namely, that bacteria could not and did not live, as a rule, in healthy human tissue. The method of the British and French surgeons took away the pabulum on which the bacteria subsisted and the bacteria were no longer able to live. In compound fractures in which they attempted to get primary union by this method they were not so successful. At Hospital No. 1, at Toule, during a quiet period they had obtained a very large degree of success in wounds of the soft parts, but here the cases were received early, were comparatively few, and the members of the hospital staff were highly trained in the application of this method. Later when active fighting began in the Argonne and at Château Thierry they were able to do no primary sutures except in knee wounds and sucking wounds of the chest. The reason for this was that it was impossible to carry out the details necessary to get primary union.

Being in charge of a course of instruction, Major Hartwell said he had tried to learn all he could by reading of what was going on in the hospitals of Europe, in which reading he had been helped by all the members of the Cornell Medical College who were associated with him in the course of instruction. As a result of this reading he had come to the conclusion that suppuration in the military hospitals of Europe had practically ceased to exist. Being unable at Bellevue Hospital to duplicate this work he had gone abroad to see how they accomplished their results. To his great surprise he found ward after ward filled with pus cases. It was just after the hard fighting of June and July when this condition existed which made it impossible to take full advantage of what had been learned. At the present time they were seeing many cases of bad suppuration in the military hospitals of New York, but that did not mean that they had learned nothing; they had learned a great deal. The suppuration seen in Paris, on the whole, was being very well controlled, and he thought it was in part because of the Carrel-Dakin teaching. The lesson that Carrel taught was the possibility of putting into practice what before we had known only from a more or less theoretical standpoint. Surgeons had drifted into a period of aseptic surgery; they were operating in an aseptic field; whether they entered the abdomen, the skull, or did a plastic operation, they were operating in

clean fields. The mistake they made was that they relegated suppurating cases to the care of the junior. A man with a suppurating wound drifted down the scale from one surgeon to another until his entire care fell to the junior or the house staff. The tendency was to hand all minor injuries to the junior. Carrel taught that by careful attention to detail these suppurating injuries could be cared for in a much better way than hitherto. He stated that not more than 10 per cent., possibly not more than 5 per cent., of the good result in the Carrel-Dakin treatment could be ascribed to the chemical action of the solution; the remaining 90 or 95 per cent. of the good result was due to care and surgical treatment. The Allied Conference of British, French, Italian, and American surgeons concluded at their last meeting that in the last analysis their success resulted from the application of the well-known old-time principle of surgery, namely, thorough removal of damaged tissue, wide open wounds, and helping nature along biological lines, without looking for great assistance from antiseptics, and that this method was the best available at the present time. The Dakin solution was excellent in cases in which suppuration was established, not because of its bactericidal properties, but because it dissolved protein matter but would not dissolve healthy tissues with active circulation. If the solution entered the wound it combined with the protein substances on which the bacteria lived, and these were washed away and removed more delicately than could be done with a knife. The important lesson in the Carrel-Dakin treatment was the minute and careful attention to detail, the placing of suppurating wounds in an important category, and the having them cared for by older responsible men who taught the technique to the younger men.

One of the most important results of the war so far as surgery was concerned would be the better care of cases of industrial accident. As an illustration of what this would mean Major Hartwell cited the instance of one insurance corporation which had been paying out $250,000 a year for the claims in accident cases. Any doctor could be called in to treat these cases and received two or three dollars for a treatment; in case of fracture he often got only twenty dollars, even if he had to do one or two reductions under ether. Last year this corporation employed a competent surgeon as consultant and adviser at a salary which the corporation considered five times more than it ought to pay. At the end of the year it was found that only $125,000 had been paid for the claims of accident cases, and while from $200 to $500 had been paid for the care of a single fracture case, the net saving had been $100,000. The older scheme caused loss to every one, and the injured man did not get the care he should have. The doctor was not well paid and the whole labor field was taxed to meet the bill. It therefore seemed that there was one thing medical schools should do—teach the student the care of the injured from the beginning of his course. Industrial accidents were occurring all the time to an extent that the average person failed to realize and medical schools could do a great deal to arouse an interest in this question. The surgeon turned over to his junior the suppurating minor injuries without giving him the instruction which he needed and to which he was entitled.

By organizing our hospitals and bringing them into relation with our educational institutions, both would be of much greater value than they were at present. Some plan should be inaugurated whereby young medical men should not be forced to leave the hospitals at the completion of their interneship to go out and struggle for a living and become practitioners of medicine and surgery instead of students. As things now were, when a young man went out from the medical college and hospital his medical education ceased. The avidity with which the young men who had gone into the army took up every opportunity for instruction, working nights and long hours, over and above their responsibility to their patients, was evidence that if we gave them the chance they would go on educating themselves. This opportunity could be given them only by making the public understand that a highly educated medical profession was essential for the public welfare. Funds should be established in large hospitals that would enable young men to remain longer in the hospitals and be paid for their services. The public would not see this unless we put it before them. Money could always be had if the demand for it was based on the broad foundation of public good. The profession and the medical schools should take up this problem and establish continued education for medical men, even to the extent that every three or five or six years they could come back and spend six months a year in educational work and give up the responsibilities and difficulties of private practice merely for the income it brought to support a family. Now, when every field for betterment was being opened and developed, was the time to put this plan into operation and it was to be hoped that our medical schools would grasp their opportunity and undertake the responsibilities that lay before them.

DISCUSSION.

Lt.-Col. CHARLES A. POWERS of Denver, after complimenting the President of the Society, Colonel Charles Howard Peck, on his excellent work in the medical corps in France, said that he felt quite at home in the New York County Medical Society, as he had been a member from 1892 to 1894. He would like to agree with everything Major Hartwell had said when he expressed the opinion that not very much in the way of progress had come out of the war, yet perhaps he differed somewhat in thinking that some advances had been made. He had been in France for two and one-half years during the war and one impression of his service there was that the problem of the sterilization of septic wounds had been solved by that surgical wizard, Dr. Carrel. At the General American Ambulance Hospital No. 1, at Neuilly, in April, 1916, there were 600 septic compound and comminuted fractures. As all knew this was a war of sepsis and the most desperate forms of sepsis. The soil of France gave out not only tetanus, but the Welch gas bacilli, streptococci, and other microorganisms. This particular hospital was a center for shattered long bones and tearing injuries of the face and neck; there were not many abdominal wounds. At that time they were beginning to use the Carrel-Dakin treatment. The speaker watched the results of this treatment during 1916 and 1917 and great progress was made so far as the results obtained in the treatment of these wounds. During the German offensive and the Allied counter offensive of July, 1918,

it took 24, 28, and 72 hours to get the wounded back in ambulances to the hospital and all were in a septic condition, and yet they found that they obtained remarkable results. He thought that the Carrel-Dakin management was the greatest thing that had come into their surgical lives. The results at this time were not the same as those seen in 1916 and 1917. Dr. Powers cited the case of one young man of his acquaintance who was hit by a shell and the buttock torn away. He came into the hospital after forty-eight hours with gangrenous area the size of a dinner plate. Under debridement and the Carrel-Dakin treatment the wound was sterilized in from two to three weeks and was then sewed up under an anesthetic and the sutures held. He was sure he was free to say that he had never seen a result like that in a case of that sort under the older methods of treatment. Such instances repeated themselves almost daily, especially in wounds of the leg, arm, shoulder, etc. If this entire problem of sterilization and secondary suture was not entirely new he hoped Dr. Hartwell would tell him. Dr. Powers then spoke of the management of septic joints by Willems of Ghent. He said that at the Interallied Conference of Surgeons in April, 1918, Willems showed some twenty Belgian soldiers to illustrate the management of septic joints, and they were so surprising that they made a great impression on all who saw them. All agreed that the results were better than any they had ever seen before. If one assumed, for instance, a young man with a wound of the knee, with or without fracture, made by a machine gun shell and showing all the evidences of sepsis, in such a case Willems made a free incision on the inner side and another on the outer side, letting out the pus and septic contents, washed out the joint, put in no drainage, and in eight or ten hours after this operation the man was asked to actively move his knee joint, and to move it every four hours during the day and every four hours at night if he was awake. He soon gained confidence and the pain became less every time he moved it and he thus pushed out the pus and drained his own kneejoint. It seemed that this was an entirely new method of managing cases of this sort that Willems had presented to them. With a septic elbow the arm was moved, and all these cases were ambulant. At Neuilly they put this method into practice in the management of septic knee joints in 25 or 30 cases, and while he could not give the exact data the general impression was that they had obtained much better results than ever before. So he was a little more optimistic than the speaker of the evening, and while he felt that the surgery of war was not a good form of surgery we had nevertheless gotten certain things out of it.

Dr. Howard Lilienthal said that he believed that Major Hartwell had been a little too pessimistic, although strictly and scientifically speaking he was right. When the question came down to new principles they would have to go pretty far back, for there had been no new principles brought forward for many years. While it was true that no actually new principles were brought out by the war, there had been a scientific and wholesale application of well-known principles modified in such a way as to bring about results which, if history could be believed, had never before been equalled in any other war. For instance, advances had been made in the methods of treating injuries of the knee joint. He had seen men walking about with the knee joint open so that one could see the articulation. The war had brought to the front the method of operating on the knee joint, closing the wound and allowing the patient to move the knee. In case of suppuration where the wound had to be reopened operations and resections were now done that would not have been thought possible before the war, and the patients recovered. While the Carrel-Dakin treatment was founded on an old principle it seemed entirely new because no one had been bold enough to use it until Carrel had shown them how it could be used. So far as the Dakin solution went, that was not the important thing at all, the important point was the painstaking care by people who were thoroughly trained in every detail of the method. The same surgeon dressed a wound every time it required dressing and learned to know every hole and corner of that wound and how to get it clean, and that was better than having the dressing done first by one man and then by another. As to the front line and base hospital surgery. One could not get much idea of results from the figures given at the front line, because the wounded men were sent back from the front line to the base hospital and there received the real surgical treatment in cases in which the surgeon at the front had been unsuccessful as to the immediate result. The surgeon at the front did not realize that the man he had operated on might have to be operated on again for the same little injury and might even die from it. As an illustration of this he recalled one case in which a man had been wounded by a high explosive and several foreign bodies were removed, but one piece of metal was left in the tibia. Three weeks later the little sinus unhealed, it seemed a simple matter to take that piece of metal out, but gas gangrene followed its removal and the man lost his leg. As to the matter of muscle extirpation in gas gangrene the principle was known before the war, but its wholesale application, such as the removal of the large muscles of the arm or leg, even the biceps and the quadriceps femoris, looked like a distinct advance. This war certainly had shown what surgery could do as no other war had done.

Dr. Sherwood thought it was understood the Carrel-Dakin method could be properly carried out only by men specially trained for this work. He had had the opportunity to observe a group of men who were not adapted to the work. To be successful with this method a man must have a great deal of enthusiasm and a perfect equipment, and he must have assistants and nurses who were thoroughly trained. He was surprised to hear that they must remove all fragments of shell in bone, because he had seen *x*-rays showing foreign bodies in the bone in which the condition seemed to be entirely benign.

Major Hartwell, in closing, said he evidently had been somewhat misunderstood. He thought he had made the statement very clear that no new principles had been evolved by the war but that the opportunities for the practice of known principles had resulted in a great improvement so far as results were concerned. While he was loath to disagree with Dr. Powers he did not think the chemical treatment of wounds was a new principle. He felt sure that what he had said was that what the Carrel-Dakin treatment had done was to call attention to the fact that we must use antiseptics properly and with detail. He did not intend to give the impression that the Carrel-Dakin treatment was not an improvement, for he had turned one ward at Bellevue over exclusively for the use of that method. He was using the same technique, the same men were dressing the same cases every day and he had taken the best men on the staff for this work. They were dressing the wounds in the same way that Carrel did, had the solution tested in the same way, and made the bacteriological examinations. It was a good thing and if one spent enough time in applying the treatment he could accomplish a great deal with it, but it was not a new principle. The treatment of knee joint injuries by having the patient move the knee was a new principle, but he was not convinced that it was one that would stand the test of time.

The Chairman, Colonel Peck, said he agreed with what Major Hartwell had just said. He had seen a number of joints treated by that method and later amputation had been necessary. He had also seen cases here that had been treated in that way and all had stiff knees. He had tried his best to put this method of treatment into effect, but without success. It was possible that he did not do it in the right way. It was, however, a new principle if it proved its efficiency. At Château Thierry there was no hospital near the lines and at one place there were 250 wounded men out all night in the rain. Of course these wounds were infected and cases of that kind were not a test of surgery. They were now getting many of those cases here. The enthusiasm of the surgeons for the work they were doing was unbounded and they had shown themselves very desirous of learning, and this was a great incentive to giving them the opportunity to learn after the war was over. All the subjects discussed tonight were things that should be taught in the medical schools and among them the Carrel-Dakin method should be included.

THE INTERNAL ADMINISTRATION OF THE MEDICAL SERVICE OF A BASE HOSPITAL.

By Major ROBERT H. McCONNELL,

NEW YORK.

M.C., U. S. ARMY.

In attempting to place before the minds of the men who have not had the great privilege of serving in an army hospital, the various points of interest in the administration of a medical service, one is confronted with rather a difficult problem, and that is to make it an interesting paper, and not merely a paper of statements and bare facts. To those of us who have been in one of these great institutions, the mention of the subject alone will always appeal in a manner such as no other subject can, for we feel that the experience has been one of the great events in our lives and we shall always look back to it with the greatest pleasure and happiness.

My personal experience has been one of the pleasantest imaginable. Knowledge was gained and friendships established in a manner such as one would never realize in the active practice of medicine. There is no such thing as numbers in the Army; miracles are accomplished—hospitals are built in a few hours, one learns accuracy and decision; in fact, my enthusiasm knows no bounds when I speak of these great institutions which the medical profession of the country have conducted with such success during this war. I believe that all of our civilian hospitals will feel the good effects of the training which we all have received and that many valuable points will be brought out by the various men who have been in active service.

For the benefit of those men who may not know, all hospitals have a commanding officer as head, who does the administrative work and who has his own personnel—a medical chief, a surgical chief, and a chief of laboratories. Each branch of the service has its own personnel; I will deal with the medical side only.

A chief of the medical service must be a man well versed in medicine, a good diagnostician, and a person of decision. Decision of vast importance. He must be ready to take responsibility, be resourceful and should inspire confidence; a quick, accurate decision will soon inspire the greatest confidence in those who are working in his department. In the personality of the Chief lies the success or failure of the service.

The points I wish to bring out to-night are taken from the base hospital at Camp Jackson, S. C., where I was a member of the school for chiefs of service. This was a school where men were selected from all parts of the country and trained to conduct a medical or surgical service in a base general or overseas hospital. In our training for chiefs of service we acted in all capacities in the hospital, from the lowest position up, spending a certain time in each department and acting as supervisors to the various wards. We were changed at various intervals to some other ward or would spend days with the chief of service to learn the administrative points; clinics were held three times a day on some days and at other times special work in the laboratory would take the time. In this manner one was able to see the hospital from all sides, to judge the capabilities of the various ward surgeons and rate them accordingly, and to get an insight into the inner workings of a great institution. The selection of the chief should be made with care, as some men are better fitted for a base or overseas hospital, while others may do best in a general hospital. Some men have had very little military instruction and they often fail to create confidence because they fail on the military side. One must remember that they are in a military institution and that all things are governed in a military manner. The medical officer has just as much right to the proper military courtesies as the line officer and he should demand them, not from a personal side, but for the rank which he holds. It disturbs discipline and confidence not to get the proper respect from those under him; on the other hand, he should learn the courtesies necessary and should pay strict attention to see that he carries out his part.

Chief of Service.—What are the duties of a chief of service? This is a question which has been asked many times. They are administrative and medical. He must have complete control of his service, he must know about all the severely ill patients, know the number on his service, know their conditions each day, must see them as often as possible, must look after the paper work, must follow out each man in his organization, become familiar with his work, learn his ability, and assign him to the proper station; a successful chief is the same as a successful leader anywhere else. He must have the organization, and then must see that the men do their work and report to him their results. A sample of a chief's average day is as follows: Breakfast at 7.15 A.M. Meeting with commanding officers at 8.15, lasting one-half hour. A meeting in his own office with his assistants or supervisors, where policies are discussed, plans made, cases reported for observation, announcements made, and any other matters of interest to the service taken up; this lasts about one-half hour, and after this for a short period, correspondence or paper work is done, then rounds are made with the nurse assistant, consultations are held, x-ray plates are looked at, important cases seen, and the ward surgeon's work looked into. This takes till 11.30, when a clinic may be held or a general meeting with the commanding officer in the chair. Mess 12.30. Work beings again at 1.30, paper work, conferences, more rounds with a clinic at 4. Drill at 5.15 is optional. Mess at 6.15, followed by a clinic or demonstration at 8 P.M. This makes a full day. Where there is an epidemic of some disease, the hours may be lengthened or changes made in the routine work, so that special attention can be paid to the particular subject. A chief is supposed to write on various subjects, make reports to the surgeon-general's office, keep in touch with the work done in other camps, keep his men busy arranging their work so as to maintain their interest, and in fact, doing the thousand and one things necessary and which are coming up all day long. He is appointed by the surgeon general, but is under the direct control of the commanding officer of the base hospital.

The office of the medical chief should have

medical staff consisting of an adjutant and an assistant adjutant (captain and lieutenant), and a clerical staff consisting of 1 sergeant, 3 privates, 1 head nurse to accompany him on his rounds, 2 or 3 assistant nurses, and 5 or 6 student nurses, to accompany officers. In the office of the medical chief the paper work is done, and I can assure you that there is a great deal of it. The records are kept and charts made of various epidemics or series of cases are tabulated. The adjutant or assistant is always on call so that in any emergency some one is on hand. The adjutant's duty is to stand between the chief and the many unnecessary calls that may disturb his time. He answers all inquiries and plans the work of the day for the chief up to a certain point. He takes care of and supervises the work of the office, works out with the chief the assigning of men to the various wards; in fact, an adjutant in any department of the Army has one of the most important positions that there is. He should be a man of exceptional ability and the service lies greatly in his power as to its success. His work is to assist the chief, and when I say assist, I mean just that; he should be tactful, energetic, resourceful, and intelligent. The assistant adjutant should follow in his footsteps.

The sergeant, an enlisted man, should be a stenographer and typist. He takes dictation and supervises the work of his clerical staff.

One of the privates should be an artist if possible so that pictures could be made of special cases and drawings made of various abnormalities and of interesting lesions.

The head nurse makes rounds with the chief, she carries a bag with all of the necessary things for emergency work, such as aspiratory needles, lumbar puncture needles, hypodermic syringe, cocaine, iodine, culture tubes, serum, etc., all sterilized so that he can make an examination without delay. She also takes dictation when he makes examinations and supervises the work of the other nurses. The assistants do the clerical work, and sterilize materials that are needed in his work.

The student nurses make rounds with the supervisors of the wards, taking the dictation and each one carrying a bag equipped with the same materials; this is of great help and many of the civilian hospitals would do well to follow this plan. It is a great help to the nurses as well, and it is astonishing how quickly a student nurse becomes proficient in taking the dictation; when she finds a word that she does not know or a disease or symptom strange to her, she makes a note of it and then asks later or looks it up in her books. It keeps up their interest and encourages them, giving them a stimulus in their study and work.

The assistants to the chief of medical service are briefly described as follows:

The general medical consultant, whose work is to supervise the officers' ward and be on call to see all cases of doubtful diagnosis. His work is similar to that of the medical chief, except he answers all calls, and there his work ends as he does not follow up the case.

Medical supervisors are in reality attending physicians to the various wards of a base hospital. Each supervisor is assigned to a ward or series of wards and changed from time to time; his work is to examine such patients as the ward surgeon may designate or any case he may see fit. He advises treatment, checks up the work of the ward surgeon, sees that the proper attention is being paid to the patient, discusses the case with the ward surgeon, and acts in an advisory capacity in all matters. He makes his rounds with his nurse assistant two or three times a day; and right here is where one of the most valuable parts of the whole Army experience lies. Many of these ward surgeons are experts in their own line, such as tuberculosis or neuropsychiatry, and a supervisor must work hard in order to keep the confidence and respect of these men. Another point where the service is most valuable, there is very little of the professional jealousy in a large hospital and supervisors can examine another supervisor's cases without asking and make their notes on the charts accordingly; each man must make a note on the chart when he examines a case, so frequently six or seven different men may see a case and not one has seen the other man. It does not take long to find out whether a man is careful and thorough in his work or whether he is a "bluffer." Each supervisor is checked up in his work by the chief of service and rated accordingly. If a supervisor fails to make a correct diagnosis, or in other words does not exert all of the facilities and resources to determine what is the correct diagnosis, he is liable to a court martial. He cannot afford to make a mistake; no one is infallible and he could not be blamed for not making a correct diagnosis, but he could be blamed for not doing everything in his power to make the diagnosis, and if he is unable to do so it is his duty to ask for consultations.

Specialists.—The various specialties or in other words the various subjects that have been the source of special study, such as pneumonia, meningitis, and other acute infections, neuropsychiatry, tuberculosis, and cardiovascular diseases, are looked after by men who have had training in these various subjects, and it is the duty of the chief of service to assign men as they are sent to him through the adjutant general's office to these different wards. On a man's arrival at a base hospital the chief tries to find out what he is especially fitted for, and this is done partly through his efficiency card, which he makes out himself and partly by means of conversation held with the new arrival. For instance, if a man is especially interested in neuropsychiatry, he is assigned to that division on trial, and if he is capable and fills the bill he is retained there; if not, he is transferred to some place where the chief of service thinks he may fit in. If he is medically unfit, he is given a course in some subject and trained in that line or he is given some assignment where his medical knowledge is only partly necessary. Many men are assigned to do work sometimes entirely opposite or far removed from what they had been doing in civil life, sometimes because there is no need for the particular line that they had been working on or because they would do something else better. As, for instance, I know of a case in which a very good otolaryngologist made a most expert sanitary inspector. He had a correct military bearing and had the instinct of sanitation born in him; and while he was an exceedingly good laryngologist for war purposes he

did his bit far more effectively as a sanitary expert. Again, a most efficient internist made a very remarkable property officer; he had what one might call the "property instinct," and by his methodical ways and ideas of property responsibility converted what was an apparently hopeless property tangle to an efficient and economical department. So the duty of a chief of service or commanding officer is to develop the best that is in a man during the period of his service in the Army.

The duties of the *epidemiologist* is to study the epidemiology of disease under the direction of the chief of the medical service and the chief of the laboratory, and to record the same.

The *supervisor of therapy*, under the direction of the chief of the medical service (1) has charge of the coordination of the dispensary and wards, the filling of prescriptions, the ordering of needed medical supplies and of other devices for the treatment of patients; (2) he is responsible for the adequate supply of serum vaccine and antitoxin through proper storage and distribution; (3) in the event of an important epidemic he has general supervision of its management and the publication of routine orders. In this work he cooperates with the hospital epidemiologist; (4) he also has supervision of the diets and must confer with ward surgeons, officers, nurses, and dietitians in the prescribing, preparing, and serving of food to the patients.

The duty of the *efficiency officer* is the organization of the departments and the wards of the hospital on a basis of highest efficiency. He must spend all necessary time in a given department or ward and assist those in charge in organizing it on an efficiency basis.

In a well organized hospital it is a good plan to have a supervisor of special instruction. It is his duty to arrange clinics, keep track of interesting cases, select men to present the cases and arrange classes for special instruction in various branches. This is an important position and one that can do a great deal to perfect a service by increasing the efficiency of the men, establishing classes in physical diagnosis and special instruction in the various specialties, all given along the line of post-graduate instruction. It is astonishing how popular this is; many men who have been going along in a rut for years and have been out of touch with the special branches, broaden out as this instruction opens up a new view of the practice of medicine to them. New ideas are created and they become more efficient in their own line of work. The supervisor also arranges with the ward surgeons for special training and attention to the teaching of the pupil nurses.

The *disability officer* deals with all cases recommended for limited service, S. C. D. and civilian work. He also investigates personally all cases about which inquiry is made.

The Ward Surgeon.—Probably there is no harder worked man and no one to whom greater credit should be given than the ward surgeon. His duties are manifold, he must not only look after his ward medically but also must be responsible for all property, and if any is lost must pay for it. If anything goes wrong, the blame is often thrown on him. To be a good ward surgeon, one must have medical ability and executive ability; have a knowledge of sanitation, be methodical, conscientious, a hard worker, and a man to command respect from nurses, corps men, and patients. A man could not have a higher compliment than to have it said that he was an exceptional ward surgeon, for this means a great deal. He is one of the mainstays of the hospital. He stands in the same relationship to a base hospital as a house physician does to a civilian hospital, except that his responsibilities are greater and to conduct his ward satisfactorily he must use his tact and judgment to their fullest sense.

He is responsible for: (1) Professional care of patients. (2) Condition of wards and equipment. (3) Proper performance of duties devolving upon nurses and enlisted men. (4) In case of critical illness to report to the adjutant. (5) In case of death to notify the officer of the day. (6) In case of transfer of patient to another hospital to notify the chief of service. (7) Keeping a complete clinical record of all cases under his care using the prescribed forms, also special reports on examinations such as Wassermann and gonorrheal fixation, daily, weekly, and monthly reports and notification of seriously ill cards.

The receiving ward officer has charge of the receiving ward, and when all cases, both medical and surgical, enter his duty is to distribute the cases. The vast importance of the receiving ward cannot be overestimated, for a mistake here may endanger the whole hospital from an epidemic. The receiving ward officer must be one of untiring energy, he must have an organization behind him untiring also; he must be keen, an exceptional diagnostician, and must have decision developed to a marked degree. It is often due to his care that mistakes are rectified and many medical men are saved from court martial because of his strict attention to the details of the service.

Receiving Ward System.—The receiving ward consists of three divisions 1, 2, and 3. 1. All ambulatory patients are admitted to No. 1 from the regimental infirmary. The nurse in charge enters the patient on her book, takes his temperature which is written on back of form 55a, and takes his valuables for safekeeping. Form 55a is filled out in duplicate, two laundry slips are attached, and the patient is sent to ward No. 2. The duplicate of 55a is for the registrar's files. One clothing slip stays on the patient's record; the other is attached to his clothes.

2. All patients admitted to the hospital must pass through ward No. 2. Here they are divided into two classes: bed patients and ambulatory patients. All patients with temperature of 100° or over are put to bed. All litter cases are brought directly here. Clothing is checked as soon as it is taken off the patient, and sent to the clothing room with clothing card attached. The ambulatory patients are given the shower bath; the others are bathed in bed. The ward surgeons in No. 2 examine all cases and assign them to the proper wards. Ward No. 2 keeps the admission sheet on which each patient is recorded, and the ward he is sent to is noted. This sheet is turned over to the registrar of patients daily. Ward No. 2 keeps the list of empty beds in each ward, and notes each patient sent to each ward, so that it is possible to

tell at a glance how many empty beds each ward has. Transfers fro mone ward to another must pass through No. 2 for notation.

Half of No. 2 is the colored observation ward and No. 3 is the white observation ward. Cases in which the diagnosis is in doubt are held in observation awaiting laboratory reports and consultations.

Records and Reports.—All prisoners entering hospital are sent to the prison ward and the adjutant notified. All women entering the hospital as patients must be admitted by order of some officer authorized to issue such an order; the adjutant is notified of these admissions. All patients entering the hospital for observation with a view to S. C. D. are sent to the proper ward and the chief of service is notified.

Care of Cases in Wards.—When a patient reaches a ward, he is immediately seen by the ward surgeon, a complete physical examination is made, and he is placed on treatment. If it is a simple case and perfectly clear as to its diagnosis, it remains under the care of the ward surgeon; if not, and there is a question of diagnosis or the patient is very sick, the supervisor of that section is notified and he immediately sees the case in consultation with the ward surgeon, and advises the treatment or further examination. He writes his opinion on the "progress sheet" and on his next visit follows out the case. In this manner each man is seen by two surgeons. If there is a doubt in the mind of the supervisor, he asks for a consultation with the general consultant or the chief of service; no trouble is too great or no examination too difficult in the care of these men. If the case is one of pneumonia or meningitis, or other disease such as mumps, measles, scarlet fever, etc., the case is immediately transferred to its proper place. At the termination of the disease the patient is sent to the concalescent camp and from there back to the regimental infirmary or to duty or to the development battalion for further convalescence.

Discharges.—When a patient is ready to go to duty the ward surgeon fills out his chart and sends him to No. 1 for his clothing in the morning. All patients going to duty must be ready and at No. 1 at 1:30 p. m. Here their valuables are returned to them; they are asked if they are ready for duty, and if all their clothing has been returned to them. Any difficulties are settled by the ward surgeon in charge of No. 1. Lists of patients are made out on form 45 ("disposition card") according to the infirmaries they are to go to. These forms are sent on the ambulance with the patients to the regimental infirmaries where they are signed and returned to be filed as receipts. The patient's charts which come to No. 1 with the patient at 1:30 p. m., are turned over to the registrar's office for file.

The record officer has charge of the case reports, routine ward reports, and such other records as may be required. He arranges an adequate catalog in cooperation with the epidemiologist and other members of the service, and makes a complete record of groups and individual cases of importance. He must be prepared to make a report on any epidemic or any group of cases or any individual case when called upon.

The personal officer who is the adjutant, must take care of newly arrived officers, assign them to duty, instruct them in their duties, see that they have proper quarters, and in fact do everything to put them in proper shape for immediate work.

Special Cases.—Time will not permit my going into the details of the case of each type of disease, but just a word—all diseases are systematized as far as possible. Various types of pneumonia for instance are placed in wards according to the type, whether hemolytic streptococcus, *Staphylococcus aureus*, pneumococcus, etc., cases of measles, scarlet fever, diphtheria, and other contagious diseases are isolated in separate wards. Stomach cases are taken care of by gastroenterologists, nerve cases by nerve specialists in separate wards. Lung and heart cases are placed as far as possible under specialists in these lines. In fact each disease is looked after as far as possible in a menner to produce the highest efficiency. As an illustration, no surgeon is allowed to prescribe an opiate unless he first examines the patient; again, no case of abdominal pain is allowed to continue without notifying the supervisor or chief of service. These are simply to illustrate to what degree of efficiency the care of these men has been developed.

The *x*-ray department is one of the great developments of the war, is invaluable. Besides pictures are made, chests and hearts examined without distress to patients, and marvelous plates made in unlimited quantities.

The dental department, while not under the direct control of the medical service, cooperates with it, and the dentists are there to examine all cases referred.

Summary.—I think in summing up that a few lessons could be learned from the military hospital in the conduct of our civilian hospitals in regard to (1) Organization, (2) Cooperation, (3) Thoroughness, and (4) Scientific research. Our civilian hospitals should stop the petty jealousies and quarrels that so often disturb the building of an organization. The organization of a civilian hospital can be made just as efficient as a military one if this is done through the cooperation of the various departments by the harmony of the members of the medical board with the board of directors, and with each other. This cooperation will lead to thoroughness in all the work of the hospital and from thoroughness scientific research quickly follows.

The great advantage of the military hospital is in the fact that we do as we are told without question, while in the civilian hospital if we are asked to do something, we hesitate because it may be below our dignity. I recently saw this illustrated when a certain laryngologist who attended the dispensary of a certain hospital refused to see a case in the wards because he did not have the title of attending laryngologist.

In conclusion I wish again to say what I feel all of the other members of the profession will endorse, and that is we have all gained more than we have given; we have tried to do our part, and in doing that part we have built a monument to the medical profession of this country that will last to the end of time.

HEPATIC CIRRHOSES OF SPLENIC ORIGIN.

WHEN the spleen, involved in some serious pathological process, ceases to counterbalance a normal hematopoiesis, a plethora from hyposplenia ensues and the increase in size of the spleen is a direct consequence of the polyglobulia. These splenic lesions, often of a tuberculous nature, have nothing in common with those belonging to a hemolytic spleen which also is increased in size. In point of fact, while in the first process the splenomegaly is above all passive and is to be explained as an elastic blood-reservoir undergoing oscillations of the plethora, in the second process, on the contrary, the enormous size assumed by the splenic tissue is an active phenomenon resulting from an exaggeration of the hemolytic functions. This hyperfunction may also be secondary to an affection of the bone marrow—a simple defensive reaction against an exaggerated hematopoiesis—or, on the other hand, it may be primary. In this case, the erythrophagia being exaggerated while the hematopoiesis is not, the latter remains below the needs of the economy, and the clinical picture of splenic anemia—that is to say, an anemia caused by a hypersplenia—becomes realized.

Under the term primary splenomegaly, Debove and Bruhl have described a variety clinically characterized by its insidious onset, the occurrence of painful paroxysms in the left hypochondrium (perisplenitis), extreme asthenia and anemia, and lastly, hemorrhages, especially gastric. As no case has come to autopsy, these writers have been unable to formulate an opinion as to the nature of this type of splenomegaly.

Another type of primary splenomegaly is that described by Banti, which, when typical, undergoes its evolution in three phases. In the first the spleen enlarges and a feeling of weight is complained of in the left hypochondrium, after which a moderate anemia becomes manifest. At the same time there is leucopenia. This first phase lasts for six to ten years. The second, or precirrhotic phase, is characterized by an aggravation of the poor state of the general health and the development of digestive disturbances, which probably are the first manifestations of hepatic insufficiency. This phase lasts a few months, after which the third, or ascitic, phase appears, dominated by the symptoms of cirrhosis and progressing rapidly to death, unless surgical interference arrests the progress of the process. The cirrhosis is usually atrophic. In some cases, however, an increase in the size of the liver, with or without icterus, may be met with. The most likely pathogenesis of this cirrhosis of splenic origin is that it is the result of toxic or irritating products elaborated in the spleen and carried to the liver by the portal system. With material from necropsies other writers have shown that the splenic inflammation may extend by continuity to the walls of the vein and thus attain the portal spaces in the liver. In other words, there is a true chronic splenoportal endophlebitis.

Banti is of the opinion that the affection is primarily a splenic one, basing his supposition on the preexistence of the splenomegaly in relation to the hepatic lesions. According to Oettinger and Fiessinger, the splenic lesions are the index of a hemolytic process due to blood changes. It is probable that it is the effect of a slow infection or intoxication bringing about the repetition of hemolytic acts. Whether the process is syphilitic, malarial, or tuberculous is yet obscure. Finally, there is the considerable hypertrophy offered by both the liver and spleen in phlebitis of the portal vein and the as yet badly explained cases of megalosplenia and megalohepatia of congenital origin.

STAPHYLOCOCCUS AUREUS PNEUMONIA.

THE *Staphylococcus aureus* has long been regarded as an organism of relatively little virulence, found generally in localized infections, though it has been known at times to cause a violent and serious bacteriemia. Its occurrence in bronchopneumonia has generally been regarded as a contamination, and even when found in pure culture the tendency has been to question its etiological significance. The appearance of what seems to be increased virulence of this organism has been thought to be due to a diminution in the resistance of the subject, and, strictly speaking, this is generally true. Certainly when infecting war wounds it is vastly less dangerous than the streptococci. Its importance in bronchopneumonia, hitherto slight, has been much increased as a result of the observations of Chickering and Park at Camp Jackson last fall. (*Jour. Am. Med. Assn.*, 1919, lxxii, 617). These authors made cultures from the lungs of 312 patients who died from pneumonia with the remarkable result that 153 revealed the presence of the *Staphylococcus aureus*, in ninety-two of them unassociated with any other organism. The cultures were made by thrusting a needle deep into the lung tissue and aspirating fluid into a syringe. The results were checked by examination of stained films and also by cultures made directly from the lung tissue in those instances in which an autopsy was performed. The organism was hemolytic and appeared not to differ from the usual virulent strain of staphylococcus isolated from other lesions. These findings

were so frequent and so striking that the authors examined the clinical histories of the patients and have drawn from them a clinical picture which they present as characteristic, if not necessarily pathognomonic, of bronchopneumonia due to the *Staphylococcus aureus*.

After a rather insidious onset the patient rapidly becomes critically ill with a fairly high temperature and a relatively slow pulse. Cyanosis is a pronounced symptom, the "cherry red indigo blue" color being very striking. Pain is not marked and delirium is not frequent. Epistaxis is not uncommon. Physical signs of frank consolidation are often wanting and the *x*-ray examination reveals a lobular consolidation in which the patches may be extremely small. The sputum is purulent and of a dirty salmon pink color when characteristic. There is usually a leucopenia. Complications are not frequent, probably because of the short course and high fatality of the disease. While this seems to be a fairly clear-cut picture, it is probable that it would fit many cases of pneumonia, not due to the staphylococcus, as seen at other camps. Pathologically there has been noted a definite tendency to the formation of abscesses in the lung. The treatment is symptomatic and the prognosis very grave. The authors regard the staphylococcus in these cases as a secondary invader growing rapidly in the tissues of those patients whose vitality has been tremendously lowered by the organism causing what we call influenza. It is not known whether similar bacteriological results were obtained at any other camps, but it was apparently true that certain secondary invaders were characteristic of certain camps, though the reason has not been discovered. It is possible that with the subsidence of this epidemic the staphylococcus will again become of negligible importance in bronchopneumonia, but it is necessary to remember the possibilities of the organism and to appreciate that it may produce a form of the disease which has been described as characteristic.

A DEFECT IN THE MEDICAL LAW.

ANY one who takes the trouble to scan the advertising pages of some of our daily papers, especially the Sunday editions, and of the foreign language press, will be struck with the philanthropy of several members of our noble and altruistic profession. So anxious are they to help their suffering fellows that they spend large sums (in one instance said to be $1,000 a week) to inform the sufferers where they can be cured. One of these gentlemen recently attracted the attention of the *New York Tribune*, one of whose reporters was sent to visit him. The doctor has two offices, one in Brooklyn, the other in Manhattan. The reporter visited the Brooklyn office first and there learned that he was suffering from serious cardiovascular trouble with a blood pressure of 160 and a pulse rate of 162. The treatment necessary for a cure would take three months at $50 per month. Three-quarters of an hour later the reporter was in the Manhattan office and there learned that the heart was absolutely sound, but that the lungs were "infiltrated," a condition which might readily pass into consumption; in this case the patient was told he could be fixed up all right in one month for $55.00. The proprietor of this twin establishment is a graduate of the N. Y. University Medical School and a licensed practitioner. The *Tribune* states that he formerly practised in Chicago under another name, which is a cause for revocation of license, and that he left that city after an exposure of his methods by the *Chicago Tribune*. Here he advertises and practises under his own name.

We don't know whether or not this man's methods have been brought to the attention of the officers of the County Medical Societies of Kings and New York, and we don't know what could be done if they have been. The medical practice law of this State does not forbid advertising, and even indirectly sanctions it in the clause which says that "any person who shall practise medicine or advertise to practise medicine under a name other than his own, or any person not a registered physician who shall advertise to practise medicine, shall be guilty of a misdemeanor." The law provides for a revocation of the license of any practitioner of medicine who is guilty of any fraud or deceit in his practice, or who is guilty of a crime or misdemeanor, or who is guilty of any fraud or deceit by which he was admitted to practice. It is clear the man cannot be proceeded against simply because he advertises, and it might be difficult to convince a jury that he was guilty of fraud or deceit because two of his assistants made two contradictory diagnoses, and both manifestly wrong. It is doubtful whether a law declaring it illegal for a medical practitioner or an association of medical practitioners to advertise could be passed, for it would encounter strong opposition both within and without the medical profession. So long as an association, counting among its directors an ex-President of the United States and a professor of Yale University, can fill pages of the Sunday papers with scare stuff urging the public to come and be examined before it's too late, apparently ignoring the rights of this public's private physicians, it would be manifestly inconsistent to prevent a licensed physician, advertising under his own name, from doing the same thing. It might, however, be possible to find some means for putting an end to such improper practices, and, as is shown in our news columns, the New York County Medical Society is ready to do what it can to abate this evil and to institute proceedings against those advertisers who can be proved guilty of fraud.

EDUCATION OF THE ORGANIC FUNCTIONS IN INFANCY.

THE feeding and management of an infant exert a great influence over its organic functions. Therefore the working of the digestive functions of a child depends largely upon the amount of intelligence applied to the choice of its diet and the man-

ner of its feeding generally. Dr. Eric Pritchard, writing in the *Medical Press*, March 19, 1919, on the education of the digestive functions of the infant, points out that the environment of the newborn infant is largely under the control of human intelligence. When this intelligence is wisely directed the results are good, when unwisely the results are bad. He goes on to say that instances are met with frequently in which the digestive functions have been seriously disturbed, perhaps with permanent results, owing to faulty methods of feeding or management which have been applied during the first few days of life. Moreover, and this is an important fact, most of the symptoms which are associated with digestive disturbances are manifestations of faulty motor functions, and not necessarily due to any failure of the gastric, pancreatic, or intestinal ferments to play their physiological part in the processes of digesting food. These motor functions can be educated to act smoothly and harmoniously. The motor mechanisms of the stomach are apt to be wrongly developed by faulty feeding. During the first few days of life breast feeding evolves the gastric functions favorably by the education afforded by colostrum. After three or four days of life this colostrum is converted into ordinary milk and calls the normal functions of the stomach into play. Pritchard deprecates any attempt to short-circuit this gradual educational process and states that he constantly meets with cases of pyloric spasm in young infants which has been caused by giving unduly large amounts of diluted cow's milk during the first few days of life. He goes so far as to say that any case of pyloric spasm which can be subsequently cured need never occur, and as he has seldom met with a case which has defied treatment, he is inclined to doubt that they need really occur.

Constipation or looseness of the bowels is, to a great extent, a matter of education. The bad custom of giving a dose of castor oil during the early days of life is likely to result in the establishment of faulty and incoordinated reactions. Meconium is the natural means supplied to educate the rectum in the functions of defecation, and if this is immediately discharged by castor oil purgation, the means whereby the rectal and anal muscles learn to practise their periodic duties has been lost or impaired. In short, it is obvious that, if the motor functions of digestion are not properly educated during the earliest days of life, the future of the child may be greatly imperiled; as so much depends on physical efficiency and constitutional soundness.

The Prevention of Typhoid Fever.

Owing to the precautions taken, typhoid fever has been a factor of no particular importance so far as the medical aspects of the war are concerned. This comparative immunity of the Allied armies on the western front to epidemic typhoid fever has been ascribed, and rightly, to sanitary and hygienic measures efficiently carried out and to antityphoid inoculation, but with regard to the influence exerted by each of these methods opinions differ. Some have been inclined to attribute to vaccination effects which are not justified by a close investigation of the subject. Antityphoid vaccination has been proven to be of the greatest value, but, on the other hand, it cannot be looked upon as a substitute for sanitary measures. That is to say, while both these preventive methods are of the first moment, sanitary measures are absolutely essential and vaccination is valuable. In Public Health Reports, of March 28, 1919, this point is strongly emphasized by Colonel Walter D. McCaw. Typhoid and paratyphoid fevers are increasing in the American Expeditionary Forces, and it is insisted upon that vaccination is a partial protection only and must be reinforced by sanitary measures. Colonel McCaw warns that faulty conditions of sanitation that may not be dangerous now will become serious menaces when the warm weather sets in. The means of conveyance are water and food, both of which under the conditions of army life may be easily contaminated, water by drainage from latrines and indiscriminately deposited defecations, and food by hands of carriers and by flies infected at the latrines and by uncovered feces. Consequently, in order to avoid a serious outbreak of typhoid fever in France it is incumbent upon the medical officers to see that every necessary mode of safeguarding the water and food supplies is taken and rigidly enforced. It would be a calamity if a big typhoid outbreak should occur from any slackness or negligence on the part of army medical officers in using sanitary precautions or by relying too greatly upon the preventive virtues of vaccination. This method is good so far as it goes, and should be employed in conjunction with proper sanitation and hygiene. These constitute the first and most important line of defense. and neglect in carrying them out to the last letter may result disastrously. The warning voiced in the Public Health Reports is timely and should be taken to heart by civil as well as military medical authorities.

News of the Week.

New York Newsstands for Cripples.—An amendment has been made to the city ordnance relating to the granting of new licenses for newsstands within stoop lines and under elevated railroad stations, presented to the Board of Aldermen. It was drawn up by a committee of the Red Cross Institute for Crippled and Disabled Men, and is designed to open an avenue of self-support to disabled soldiers and sailors and those physically handicapped as a result of accidents or disease contracted in civil pursuits. This amendment provides that hereafter all newsstand licenses, except renewals of existing licenses to the same person, shall be issued to honorably discharged soldiers and sailors and to other handicapped persons.

Prof. Francis Carter Wood, Director of the George Crocker Special Research Fund, Columbia University, lectured on April 15 before the members of the Georgia State Medical Association and the students of Emery University, at Atlanta, Ga.

The Harvard Medical Society of New York City will hold the only meeting of this season at the

Harvard Club, 27 West Forty-fourth Street, Saturday evening, April 26. Dinner will be served at 7.30 o'clock, after which there will be a special meeting of welcome to hear the experiences of members who have been in the army or navy medical service.

Charitable Bequests.—By the will of the late Charles McElvaney of Philadelphia, bequests of $1,000 each are made to St. Mary's and St. Agnes' Hospitals.

Moving Against Advertising Physicians.—The following resolution was passed by the Comitia Minora of the Medical Society of the County of New York, at its regular meeting, April 14, 1919:

Whereas, The Counsel of The Medical Society of the County of New York made an extensive examination and survey of the medical advertisements for a given time that appeared in the foreign language newspapers published in the County of New York, as well as in the English language newspapers, and prepared a complete list of the names of registered physicians whose advertisements appeared therein, and

Whereas, Most of the papers published in the English language in said county have cooperated with this Society in the suppression of fraudulent medical advertisements, and

Whereas, It is desirable in the interests of public health that the public should not be misled or victimized by false or misleading medical advertisements, and

Whereas, The Health Department of the City of New York has, from time to time, called upon the Counsel of this Society for cooperation in the suppression of such types of medical advertisements;

Be It Resolved, That The Medical Society of the County of New York, through its Counsel, render such assistance as is possible to the Health Department of the City of New York and to the other duly constituted authorities in said city, to suppress by proper proceedings such medical advertisements and to prosecute those against whom legal evidence may be found, who by means of such advertisements may be guilty of fraud or other illegal conduct.

A Physician Sent to Jail for Speeding.—A sentence of ten days in jail and a fine of $100 for speeding, imposed upon a physician of this city in the Adams Street Police Court, last January, was upheld last week by Judge May in the County Court, in Brooklyn. The physician claimed he was on his way to visit patients, but the court held that "a physician has no rights upon our highways superior to those of any other motorist." An emergency, he said, might occasionally confront a physician who was called in a life or death case, where his haste to give relief might be partially excused or entirely overlooked, but as this was the sixth offense of the accused it was not possible to overlook it.

Citations for Distinguished Services.—Col. Ernest G. Bingham, U. S. Army, has received the Distinguished Service Medal for exceptional meritorious and distinguished services as chief surgeon of the Paris District, where he most efficiently coordinated the work of the hospitals and ambulance trains in the Paris Group during the second battle of the Marne.

Lieut. Arnold D. Tuttle of San Francisco received the Distinguished Service Medal for exceptionally meritorious and distinguished services in his capacity as assistant to the chief surgeon, and later as member of the General Staff, A. E. F. He superintended the preparation of hospitalization plans and their execution, and assisted in the evacuation of the sick and wounded from the battlefield in such a manner as to greatly increase the efficiency of his department.

Col. Fred T. Murphy of St. Louis has received the Distinguished Service Medal for meritorious and distinguished services. As director of Base Hospital No. 21, as supervisor of the evacuation of the sick and wounded of the First Army, and later as director of the Bureau of Medicine and Surgery of the American Red Cross, he rendered most valuable service to the A. E. F., displaying unusual administrative and professional ability and a genius for organization which contributed greatly to the efficiency of the medical service of the army.

Lieut.-Col. Joseph M. Flint of New Haven, Conn., has received the Distinguished Service Medal for exceptionally meritorious and distinguished services when placed in a position of great responsibility as commanding officer of Mobile Hospital No. 39, Aulnois-sous-Vertuzey, France, where he used extraordinary skill and sound judgment in the organization and operation of that unit, the first of its kind in the A. E. F.

Col. Burton J. Lee of New York has been awarded the Distinguished Service Medal for exceptionally meritorious and distinguished service as surgical consultant attached to the Second Division. He served continuously at the front, organizing his forces for the treatment and evacuation of the casualties with unusual skill and marked success. He displayed unusual ability in the operations before Soissons, when in an emergency he organized and personally led and directed surgical teams which cared for hundreds of wounded soldiers, at a time when adequate hospital facilities could not be established.

Hospital Unit for Turkey.—The American Women's Hospital, which has been operating a hospital at Luzancy, France, and maintaining a chain of dispensaries in the country around Soissons and Chateau-Thierry, is now launching a campaign to raise $250,000 to be spent in the Near East. It is planned to establish a hospital at Aleppo. A unit of six doctors has been selected; they will be the first women to be put in charge of a hospital in the Turkish domain.

Tribute to War Nurse.—Brigadier General Francis Winters, M. C., U. S. Army, in a special communication to the press calls attention to America's gratitude to Miss Jane Delano, who died at Base Hospital No. 8, Savanay, France, on April 15. She was formerly superintendent of nurses at Bellevue Hospital, New York, coming into the army in 1908, in response to an appeal from the Surgeon General for help in reorganizing the Army Nurse Corps. Later she took the direction of the Red Cross Nursing Service and went to France in that capacity. Brig. Gen. Winters compares Miss Delano's work to that of Florence Nightingale, and suggests a fitting memorial in the Red Cross Building in Washington.

Restless Students.—April 9 was a day of unrest for students in South America. In Buenos Aires seven thousand high school students went on strike to enforce their demand for the abolition of entrance examinations in the National University. In Rio Janeiro the students in the law and medical departments of the National University of Brazil went on strike demanding free passes on the street cars.

Medical Examination of Employees of Armour & Company.—Plans are being made by Armour

& Company for the renewal of the medical examinations of the 12,900 men and women working in the Chicago plant of the company, which was discontinued during the war. Dr. Volney S. Cheney and his assistants will have charge of the work.

Doctors Fight Health Insurance.—The Medical Society of the County of Rensselaer (N. Y.), which is opposed to the health insurance measure before the Legislature, is incensed against Senator John J. Mackrell of that district because he voted for the bill and is reported to be making plans for his enforced political retirement.

Medical Society Elections.—The NEW YORK SURGICAL SOCIETY, at its annual meeting, held April 9, 1919, elected the following officers for the ensuing year: *President*, Dr. William A. Downes; *Vice-President*, Dr. John A. Hartwell; *Secretary*, Dr. Ransom S. Hooker.

The HOMEOPATHIC SOCIETY OF THE STATE OF NEW YORK, at its sixty-seventh annual meeting, held in Brooklyn on April 7, elected the following officers for the ensuing year: *President*, Dr. Roy Upham of Brooklyn; *First Vice-President*, Dr. Arthur S. Grant of Utica; *Second Vice-President*, Dr. Samuel B. Moore, Manhattan; *Third Vice-President*, Dr. T. D. Buchanan, Manhattan; *Secretary*, Dr. Grace Kahrs, Manhattan; *Treasurer*, Dr. Gertrude G. Mack, Manhattan; *Necrologist*, Dr. Glen I. Bidwell, Rochester; and *Counsel*, Edwin Van Wormer, Albany.

The ST. LOUIS PHYSICIANS AND SURGEONS' SOCIETY, organized on April 1, 1919, elected Dr. L. C. McElwee *Chairman* and Dr. H. Grosby, *Secretary*. The society held its first meeting on April 7.

Government Survey of Drug Addiction.—A special committee, composed of G. C. Keith, deputy commissioner in charge of narcotics of the Internal Revenue Bureau at Washington; Professor Reed Hunt of the Harvard Medical College, Dr. A. G. du Maz of the Public Health Service, Lieut.-Col. Pearce Bailey of the United States Army Medical Corps, and Representative H. T. Rainey of Illinois, appointed by the Secretary of the Treasury to make a national investigation of the drug habit, have recently submitted a survey. This report seems to show that native born Americans are more prone to the drug habit than other white races, and that the drug habit is more widespread in the United States than anywhere else on earth. In some parts of the country, notably in large cities like New York, Philadelphia, and Pittsburgh, the liquor and drug habits were found to be gaining more victims side by side, while in other parts of the country, where prohibition had gone into effect, extensive use of paregoric and similar compounds containing morphine was discovered. In Jacksonville, Fla., 800 drug victims were found out of a population of 7,000. The number of drug victims were found out of a population of 7,000. The number of drug victims in the United States is estimated at not less than 1,500,000. There is no part of the country without them and no State where the growing evil has not been a problem. The experience of the war shows that excitement and overstimulation is responsible to some extent for the increase in the use of drugs. The report points out that if drug addiction is to be controlled the individual States will have to pass supplementary legislation, and thus far only three States have done this, namely, New York, Massachusetts, and Tennessee. In seeking to prevent the drug evil from extending its grip when prohibition goes into effect the authorities at Washington propose to seek the closer cooperation of physicians.

The Drug Campaign in New York.—The New York City Branch of the State Narcotic Commission has opened an office in the Department of Health Building, and intends to open clinics in this city and throughout the State, working in cooperation with local health boards. A clinic has been opened in Albany. The clinics in New York City will be temporary, and arrangements will be made with the hospitals for the after care of drug addicts. The Worth Street Clinic, which was opened about a week ago, has treated 3,931 drug addicts, an average of about 700 daily. The Health Department will open no additional clinics at present, but will continue to conduct the clinic at 145 Worth Street. Statistics taken from 214 drug addicts visiting the clinic show that most of them are engaged in unskilled occupations. Thirty-four pursuits are represented. There were four doctors, a newspaper man, and a teacher among the number. At least 20 per cent. of these addicts were employed in transportation work. This constitutes a menace to the traveling public and steps are contemplated to prevent the employment of such persons by transportation companies. Dr. Walter B. Herrick has been appointed chairman of the State committee.

St. John's Guild Seeks Funds.—St. John's Guild, which for the past fifty-two years has maintained the Seaside Hospital at New Dorp, Staten Island, and operated the Floating Hospital, has begun a campaign to raise $150,000 for a nurses' home at the Seaside Hospital. An anonymous donor has offered to donate $50,000 of this amount provided the trustees can raise an additional $150,000.

Dr. E. S. Loiseaux, City Bacteriologist of Sacramento, has been appointed medical superintendent of the Sacramento County Hospital.

Vacancies for Physicians.—The New York State Civil Service Commission announces that examinations will be held on May 24, 1919, to fill the following positions: Bacteriologist, Department of Health, men only, between the ages of 25 and 40 years. Applicants must have a degree in medicine or an equivalent education and a thorough knowledge of the principles of bacteriology, immunity, and vaccine and serum therapy, and must have had considerable practical experience. The position carries a salary of $2,000 to $2,500. Assistant bacteriologist, Department of Health, for men only, between the ages of 21 and 35 years. Candidates should have a collegiate education or its equivalent, and thorough knowledge of the principles of bacteriology and infection and immunity, together with practical experience in the bacteriological diagnosis of infectious diseases. The salary is from $1,200 to $1,800. Assistant physician, regular or homeopathic. This examination is intended to provide eligibles for the position of assistant physician in the State hospitals and for other positions of a similar nature in various State and county institutions. Applicants should have had at least six months' practical experience on the resident staff of a general hospital or as medical interne in a State hospital, or have been engaged at least one year in the

practice of medicine. The position carries a salary of $1,200 with increase and maintenance. Applications must be in the hands of the Civil Service Commission, Albany, N. Y., not later than May 14, 1919.

Obituary Notes.—Dr. H. Augustus Wilson of Philadelphia died of chronic nephritis on April 16, at the age of 65 years. He was graduated from Jefferson Medical College in the class of 1879. He became in 1879 ophthalmologist to St. Mary's Hospital, in 1880 pathologist to the Presbyterian Hospital, was from 1879 to 1892 lecturer in the Philadelphia School of Anatomy, became in 1885 assistant surgeon to the First Infantry Regiment of the National Guard of Pennsylvania, in 1888 professor of mechanical surgery in the Philadelphia Polyclinic Hospital and College for Graduates in Medicine, later professor of general and orthopedic surgery in the same institution, and since 1897 emeritus professor; in 1889 clinical professor of orthopedic surgery in the Women's Medical College of Pennsylvania, in 1891 clinical lecturer on orthopedic surgery in Jefferson Medical College, in 1892 clinical professor, and he was from 1904 to 1918 professor of orthopedic surgery; in 1900 he became orthopedic surgeon to the Philadelphia General Hospital, in 1906 orthopedic surgeon to St. Agnes' Hospital. He also served as consulting orthopedic surgeon to the Kensington Hospital for Women and to the Philadelphia Lying-in Charity. He was a member of the Philadelphia Academy of Surgery, of the Philadelphia County Medical Society, of the Medical Society of Pennsylvania, of the American Medical Association, of the American Orthopedic Association, and a Fellow of the College of Physicians of Philadelphia and of the American College of Surgeons.

Dr. George Edwin Day, retired, a graduate in medicine and dentistry, died at his home in New York on April 7, aged 85 years.

Lieut. Col. Lewis T. Griffith, M. C., U. S. Army, of New York, died in France on April 8, aged 46 years. He was a graduate of the Albany Medical College in 1897, served in the Army Medical Corps through the Spanish-American War, and later in the Philippines. He went to France in September last to take charge of Base Hospital No. 76.

Dr. Albert A. Appel of Haddon Heights, N. J., died in his office at Philadelphia on April 9, at the age of 47, as a result of heart disease. He was graduated from Hahnemann Medical College and Hospital in the class of 1898.

Dr. Joseph Cummings Poffenberger died at Sunbury, Pa., on April 9, at the age of 31 years, as a result of pneumonia complicating influenza. He was graduated from Jefferson Medical College in the class of 1912. He was a lieutenant in the Medical Reserve Corps of the United States Army, a member of the Northumberland County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. Alfred J. Becker died of apoplexy at Catasauqua, Pa., on April 16, at the age of 58 years. He was graduated from Hahnemann Medical College and Hospital in the class of 1885. He was a member of the Homeopathic Medical Society of Lehigh County.

Dr. Reuel Baker Kimball of New York and Seabright, N. J., died at the Stern Hospital, New York, on April 18, aged 64 years. He was a graduate of the College of Physicians and Surgeons in 1880, a member of the New York Academy of Medicine, attending physician to the Babies' Hospital, and consulting physician to the Monmouth Memorial Hospital, Long Branch, N. J.

Dr. James W. Harris, a graduate of the New York Homeopathic Medical College in 1882, died from pneumonia at his home in New York, on April 13, aged 72 years.

Dr. James Herman Betz of Jamaica, New York, a graduate of the Pennsylvania Medical College, and for many years an employee of the New York Health Department in Queens, died on April 17, aged 60 years.

Dr. William J. Hurley, retired, formerly of New York City, a graduate of the New York University Medical College, died at his home in Elizabeth, N. J., on April 16, aged 60 years.

Dr. John Devoe Martinez Cardeza, a graduate of the University of Pennsylvania, in 1877, and of the University of Heidelberg, Germany, formerly a practitioner of Claytown, Del., died at the home of relatives in Brooklyn, N. Y., on April 15, aged 79 years.

Dr. Norton Harkness Kirkland, formerly of New Haven, Conn., who made a special study of tropical fevers, died recently of blood poisoning at Brighton, England, aged 58 years.

Dr. Abraham Branaman, a graduate of the Kansas City Medical College, in 1898, died suddenly on April 1, aged 63 years.

Dr. Pearl Tenney Haskell, superintendent of the Bangor State Hospital, died suddenly on April 13, aged 51 years. He was a graduate of Bowdoin Medical College, in 1893, practiced medicine for ten years in Wakefield, N. H., and then became assistant superintendent to the New Hampshire State Hospital. He became assistant superintendent of the Bangor State Hospital in 1914, and superintendent in July, 1917.

Correspondence.

OUR ATTITUDE TOWARD GERMAN PHYSICIANS.

To the Editor of the Medical Record:

Sir:—The sentiments expressed in your editorial of December 14, 1918, ably championed in later issues by Drs. W. W. Keen and Charles A. Powers, suggest the following comment.

American physicians and surgeons are a unit in placing a low estimate upon the morale of the German medical profession as a body. The arrogance of the latter, their false pride, unwarranted assumption of superiority, ruthless depreciation of the achievements of men of other nations, and open violation of the established rules of ethical conduct are matters of common knowledge.

The idea of according full fellowship to German doctors "to arrive" is repulsive to most Americans. Experiences of the past four years have given us a new point of view, and we have a clearer vision of German thought emanating from their centers of learning and from individual men of science. Never again will Teutonic universities assume the

rôle of "Mecca" for the numberless thousands of students who have perennially worshipped at their shrine, and who with grave serenity have accepted their false philosophy. In a word, the non-Germanic world has awakened from a forty-year obsession.

Furthermore, we have ample evidence that the German profession as a body brazenly and unreservedly endorsed the Hohenzollern policy in the conduct of the world war. Beyond question, the doctrine of frightfulness, as set forth by Treitschke and his school, became the inspiration not only of men of science but of the German people far and wide. No word of protest in the face of atrocities fiendish and without precedence in human annals has ever come out of Germany. Entire absence of human sympathy, numberless examples of cruelty, brutality, and criminal neglect of plain duty as recognized by the humane of all *civilized* nations form a conspicuous chapter in the recorded annals of this world war.

If there be exceptions, as you intimate there may be, individuals have failed through inadvertence (?) or cowardice to voice their protests. In reviewing the vast chronicles of inhumanities and horrors we have reiterated assurances that the German people are one in sentiment.

Col. George Harvey authorizes the statement that the Universities of Leipsig and Heidelberg have had the effrontery to ask the Universities of France for a resumption of pre-war relationships. This request was made on the theory that there are no racial or national lines of demarcation in the world of science. The French rejoinder is forceful if not final in its suggestiveness. Freely paraphrased, it is as follows: The most scathing indictment of the German people rests upon the fact that they do not appreciate the enormity of their moral wrong. Let them seek an answer to their cringing demand from the people who were driven from the battle zone of France, who were ruthlessly robbed of their homes, their fortunes, and their lives under the pernicious doctrine that might makes right. They best understand the depths to which the German mind can descend.

It cannot be doubted, as Dr. Powers states, that the German profession is already insidiously paving the way for reinstatement in American medical organizations and for reestablishment of full fellowship with the medical profession.

Americans will act wisely in adopting the attitude of their colleagues in pallid, war-worn France, the noblest of all our allies, who know best the moral degradation of men who have lent their approval to the unspeakable philosophy of the "Fatherland." In my opinion this matter can be safely left for final adjustment, first to the individual American physician, and finally to our most representative judicial body, the American Medical Association.

THOMAS W. HUNTINGTON, M.D.
SAN FRANCISCO, CAL.

Mitochondries and Symbiotes.—Regaud states that between mitochondries and ordinary microorganisms there are no essential differences, but numerous superficial distinctions, the former being readily deformed and but slightly resistant to mechanical, chemical and autolytic agencies. By mitochondries he means the symbiotes of Poirier.—*La Presse Médicale.*

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, March 27, 1919.

Pensions to Hospital Doctors.—Shortly before the war, in the spring of 1914, the executive committee of King Edward's Hospital Fund for London appointed a sub-committee to consider the question of pensions for hospital officers. The sub-committee consisted of Mr. W. J. H. Whittall, Fellow of the Institute of Actuaries, who acted as chairman, Mr. H. L. Hopkinson, and one well-known medical man, Sir William J. Collins, M.P., who is also an ex-chairman of the London County Council. The enquiry was held at the instance of the Hospital Officers' Association, who submitted to the sub-committee a statement of the hardships suffered by hospital officers by the lack of ability to make proper provision for old age or retirement; and the terms of reference were "to enquire into and report as to the existing provision for pensions for officers and staff employed in the London voluntary hospitals, and to recommend changes of extensions of the existing arrangements." The enquiry, it should be added, was welcomed by the London hospitals, which institutions were consulted by circular letter in order to ascertain their opinion of the movement. The replies to the circular letter indicated that the enquiry would be very generally welcomed, and that there was reason to believe that any practicable suggestion for getting over the difficulties in the way of securing pensions, particularly in the case of medium-sized hospitals, would receive the sympathetic consideration of the various hospital authorities. The report, which has now been issued, investigates fully the difficulties that arise in providing pensions in the case of hospital officers, which difficulties are specially indicated by the meager provision to such an end as at present exists. While the principle of pensions for hospital officers is generally recognized, and while at some hospitals there are schemes in force there is no regular pattern for making such provision, individual cases being treated as requiring a special act of benevolence on the part of the managing authorities.

It became evident in the course of the enquiry that migration from the service of one hospital to that of another involved the loss of all claim to pension resulting from years of service at the first hospital, while on general grounds the grant of pensions to superior officers deranged the finances of institutions which exist for the dispensation of public charity. With this last objection the sub-committee deal succinctly in their report. They state the objection to the gift of money, subscribed to hospitals for the treatment of the sick poor, being used in the grant of pensions, only to dismiss it as based on a confusion of ideas. "The grant of a pension," they say, "is not an act of charity involving a diversion of the funds of the hospital from the particular charitable purpose for which they were given, ... it is the method of paying to an officer a certain portion of the remuneration which he has earned, and the payment of which is part of the ordinary expense of carrying on the work." They then analyse the schemes that exist for the granting of pe-

sions in the six London hospitals where such schemes are in operation, later discussing the position at the ninety-nine London hospitals which have no such schemes. The six London hospitals with general pension schemes are St. Bartholomew's, the London Hospital, Guy's, Middlesex, St. George's, and the Cancer Hospital, all of which large institutions have endowment, though the charities benefit to a very variable extent by such private income. The pensions at these six hospitals are based on the usual Civil Service pension scheme laid down by the Superannuation Act, they are non-contributory, and are calculated at a certain fraction of the final salary for each year of service up to a maximum of two-thirds of the final salary. Dealing with the hospitals without schemes, the sub-committee classifies the pensions paid in 1913 to the total staffs, salaried staffs and weekly-wage staffs, when it is at once seen that in the 99 hospitals without schemes, only seven salaried officers retired from age, and those officers received on the average less than one-seventieth of the salary for each year of service, as against the proportion of nearly one-fiftieth in the hospitals with schemes.

The uncertainty and lack of uniformity in any existing provision of the London hospitals for the granting of pensions is made completely clear by careful analysis supplied in the report. The sub-committee endeavor to analyze and correlate all the methods by which pensions are granted under existing schemes, classifying them according to the method of financial provision; they then apply these experiences, thus brought together and analyzed, in order to answer the fundamental questions. Their final recommendation is that a joint conference of hospital representatives should be invited to consider the whole question of a scheme "based upon recourse to insurance companies." They reject "the mutual principle" unless a sufficient financial guarantee can be provided outside the mutual fund; and this the hospitals are unable to ensure. They recommend that in addition to the hospital staffs and officers, care should be taken that the nursing staffs and weekly-wage class are separately represented and that experimental calculations should be based on a ten per cent. contribution, each party to the pension scheme paying five per cent. Such a scheme, of course, would be obligatory upon all accepting new appointments. In cases of existing staffs a similar total contribution would have to be made on mutually agreed terms for each year of future service, a procedure which would greatly reduce the cost of private pensions in arrear. The sub-committee recommends that in order to raise the status of hospital service every year of work should command a vested right to pension, so that the benefits of any existing policy would follow the officer either on withdrawal generally or on migration to another institution.

This is the general recommendation of the sub-committee, but in a dissentient memorandum Sir William Collins finds himself unable to concur in the conclusion that a scheme based on a recourse to insurance companies is the only possible solution of the problem. Sir William Collins considers that the conference of hospital representatives which will follow upon the report should have before it not only the plan based upon the methods of insurance companies, but the various alternatives presented in the report, such as the Civil Service and other State Service patterns, the pattern adopted by the police, and the asylum officers, and the schemes of great railway companies, where, for the most part, the amount of the pension depends upon the officer's future salary. He recalls in his memorandum the fact that pensions to officers are already regarded by King Edward's Hospital Fund as legitimate expenditure of hospital revenue, quotes the statutory powers of the fund in respect of its general funds and gifts for special purposes, and suggests that if the King's fund by subvention or guarantee were permitted to render financial aid, a mutual scheme would become feasible.

The whole report is a most valuable document, because it brings within the covers of a readable book the causes and details of much financial disorder and much injustice known to exist in the management of these great charities, and known moreover to exist there to the extreme dissatisfaction of all the authorities concerned. Every one is aware that hospital officers deserve pensions; the result of this close investigation of the circumstances should be prompt reform.

The Exclusion of Ireland from the Operation of the Ministry of Health Bill.—The exclusion of Ireland from the operation of the Ministry of Health Bill was a tactical error. It conveys the impression that the public health of Ireland is of less concern to the empire than the public health of other possessions and divisions of the kingdom. The Attorney General for Ireland is accordingly proposing to press for the inclusion of Ireland in the bill.

The Diminishing Population of England and Wales.—In the last quarter of 1918 the number of civilian deaths in England and Wales actually exceeded the number of births by 79,443. The message of the Registrar General, concealed behind these figures, is that pestilence has recently taken the place of war in reducing population. It is true that 8000 more births were registered than in the corresponding quarter of 1917, and that the period in question corresponded with a devastating pandemic of influenza, but that in any period like a quarter of a year the deaths should exceed the births is unknown in England in modern times.

CANADIAN LETTER.

(From an Occasional Correspondent.)

MONTREAL, April 14, 1919.

Federal Department of Health.—Although the war has not exerted a direct influence upon the movement for the establishment of a federal department of health for Canada, it has exerted a strong indirect influence. That is to say, the question of such a department has been discussed for some considerable time, and there is little doubt that the project would have come to pass in the course of time, but the events of the war have greatly hastened the decision of the Cana-

dian Government to create a department of this nature at once. The speech from the throne at the opening of the present session has announced that the Dominion Government is pledged to bring into being a ministry of health. Perhaps the prevalence of venereal disease among returned soldiers and the necessity for coping with the problem adequately has had a great deal to do with the prompt action. Also, there are several other matters which come within the domain of public health upon which attention has been focussed by the war and which it is incumbent upon the Government to deal with rapidly and effectually. For instance, there is the question of immigration and housing, both of which call loudly for attention. The debate in the Canadian Parliament on the bill for the creation of a national department of health was introduced by Hon. H. W. Rowell and was discussed by some well-known Canadian medical men. During the debate Mr. Rowell pointed out that figures indicative of the physical condition of Canada's young manhood, as revealed by the medical examination were not by any means encouraging. Of a total of 361,695 young men who passed through the hands of the doctors 180,440 were found physically fit, while more than half of that number, 181,255, were rejected for one defect or another. These figures disclosed the necessity for taking measures to improve the public health. Thousands of young men found unfit were probably in that condition as a result of preventable causes. Mr. Rowell also gave statistics with regard to the comparative mortality of infants under one year of age in certain countries and in Canada: New Zealand, 50 deaths per thousand babies under one year of age; Australia, 68; Sweden, 70; Switzerland, 91; Denmark, 95; England and Wales, 110; France, 78; Russia, 248. In Canada, Saskatchewan, 91; Prince Edward Island, 93; Ontario, 107; British Columbia, 107; Manitoba, 113; Nova Scotia, 120; Quebec, 153. Compared with London, England, as regards the mortality of infants under one year of age, Canadian cities were as follows: London, England, death rate for infants was 89 per 1,000, while Toronto was 109; Vancouver, 126; Winnipeg, 144; Quebec, 203; Montreal, 207; Ottawa, 224. The speaker further drew attention to the fact that venereal disease was more prevalent among the civil population than among the troops. He urged that as nothing was so important to public health has good housing, so the housing scheme of the Government would be entrusted to the Department of Public Health.

Dr. Charles Sheard of Toronto, a former head of the Toronto Board of Health, insisted that it was essential to develop scientific research and laboratory work as a feature of the proposed Department of Health. As for venereal disease, Dr. Sheard advocated a most careful examination of persons coming into Canada at the port of entry. Cases of this kind should not be allowed to come into the country at all because if they were allowed, the result was injurious to the national health as well as to the national purse. If any soldiers or their relatives returned with contagious disease they should be cared for by the Federal Government. Dr. R. J. Manion suggested that the minister in charge of the department should not be a medical man, but expressed the hope that the very best public health authority available should be chosen for the position of deputy minister. He mentioned the names of three eminent medical men—Dr. T. Starkey, Professor of Hygiene at McGill University, Montreal; Dr. Amyot, Professor of Hygiene at Toronto University, and Dr. Hill, formerly of London, Ont., and now in Minnesota. His reason for hoping that the minister in charge would not be a medical man was that as a doctor he could say that the ordinary medical man had very little knowledge of public health.

Canada then is the first of the English-speaking countries to resolve on the formation of a department of health, and her example will soon be followed by England and Wales. It is a new departure of the utmost consequence, and if the bill be wisely drafted should exercise a most favorable influence on the public health. There will be a certain amount of overlapping, but that can be regulated, and there seems to be no doubt that Canada has taken a step highly calculated to advance the cause of preventive medicine. It is, however, very essential to the successful working of the scheme that medical health authorities should play a leading part in framing the bill and also in carrying its provisions into effect; at any rate, in an advisory capacity. It is absolutely true that the health of the people is the supreme law, and no trouble nor expense should be spared to foster good health among the masses. But as was pointed out editorially in the MEDICAL RECORD April 12, 1919, the medical profession should have a voice in the formation of a department of health, and politics should wield no influence in the matter which so closely concerns the health and therefore the prosperity of a nation. It may be stated that an appropriation has been made recently by the Canadian Government of $25,000,000 for housing purposes.

The Returned Medical Man.—The medical man who offered his services to his country and who thereby, to a greater or less extent, sacrificed or, at any rate, injured his future is deserving of consideration. It is, of course, a problem in Canada, as in Great Britain, and in the United States. The absence from practice has borne, and will bear, more heavily on some men than on others. For the young men of the profession it was in many instances a useful experience and somewhat of an adventure. The rich or well-to-do men did not suffer greatly materially, although they gave up a great deal. But the men who were settled in practice and were making a comfortable living and not much more, gave up practically everything, and it will be hard, indeed, if by their self-sacrifice they and their families suffer in the future. A letter on the subject has been published recently in the *Montreal Star*, written by Sir Robert Philip, president of the Royal College of Physicians of Edinburgh, and by Dr. R. McKenzie Johnston, president of the Royal College of Surgeons, Edinburgh. It is pointed out that it is one of the problems of demobilization deserving of sympathetic consideration from the public. Many doctors who throughout the war have held

commissions in the Navy, the Army or Air Force have now to face the question of return to civil practice. This is for them far from an easy matter. The natural growth of their practices has ceased during their absence in spite of loyal help given, in most instances by colleagues, who deserve all thanks for their ungrudging efforts and by professional committees to hold together the practice in the interest of the absentee, the normal wastage due to deaths, changes of residence, etc., has had the effect of materially reducing the practice from what it was in 1914. Beyond such unavoidable influences there is risk of curtailment from other causes. It is known to us that many of these who have been absent with the forces of the crown view their future with grave anxiety. In a profession like medicine, where the work is essentially personal, the future of the men evidently depends largely on the attitude of the general public. It is greatly to be hoped, therefore, that every patient will feel it an honorable duty to return, wherever possible, to the old doctor, and that public institutions will reinstate, as far as they can to their former positions, those medical officers who have sacrificed so much to the call of the Empire.

Dr. Sir Robert Philip and Dr. R. McKenzie Johnston have put their fingers on the crucial point as regards the future of the returned medical man when they say that it mainly depends on the attitude of the general public. After all, a practice is largely a personal matter, and a medical man makes his living, to some extent, by his individuality and mostly by his capacity to establish confidence. The break in the relations of doctor and patient made by the war will not be easy to cement, but if the patients are loyal to the individual as well as patriotic the returned medical man will be able to commence anew under favorable auspices.

Education in Public Health Affairs.—The people at large are beginning to become interested in public health work and to understand that in the furtherance of preventive methods lies the hope of their physical salvation. There is yet, however, a large field open for propagation of public health teaching, and it is encouraging to note that in Western Canada the authorities are well alive to the situation. Recently in the Western Provinces a series of public meetings have been planned throughout the various school districts to supplement the work of the public health nurse, to arouse and stimulate interest in the phase of public health activity, and to preach the gospel of health. According to the *Canadian Medical Association Journal*, April, 1919, the history of the new venture is brief, the movement having begun in 1916 with four nurses, which number was increased in 1917 to ten or twelve, and in 1918 to about eighteen. Fifty would be needed to cover the ground properly.

The public health nurse does no actual nursing except to give first aid. The public service nurse does visiting nursing. The provincial government, the municipality, and the school district pay each one-third of the salary of these nurses. Thirty or forty schools come under their inspection, in addition to numerous home visits which have to be paid. The aim is to secure for every school child an examination to determine physical fitness and, whenever that is lacking, to suggest to parent and child means to achieve it. The work of education goes on constantly and incidentally between school and home as a consequence of these visits. An Honor Club is established among the children not to keep any sickness a secret. The mothers are helped with hints about safeguarding young life and prevention and the golden rule of quarantine are taught effectively. In the Western Provinces the public health nurse is greatly needed on account of the sparsely populated country. In fact, she is a godsend to the sick in out of the way districts to which the visit of the medical man is necessarily a rare event.

Sanatorium in Alberta.—A sanatorium is to be built by the Dominion and Provincial governments near Calgary. The Federal Government will grant the extra appropriation of $60,000 which will be necessary to build the addition asked for by the Alberta medical profession, providing room for another seventy-five civilian patients. The total expenditure will be $460,000, of which the Dominion Government will pay $260,000, and the Province $200,000, the entire plant to revert to the latter after the lapse of five years.

The Influenza Epidemic in British Columbia.—The Department of Health of British Columbia has published recently figures showing the mortality in that province from influenza during the months of October, November, and December. Two thousand and fourteen died during these months. The figures given do not include any deaths that were not certified to as from "influenza" or "pneumonia following influenza." Other forms of pneumonia are not included. The percentage which the deaths from influenza or from pneumonia following influenza bore to the total deaths from all causes was 43.05.

5. Circulatory Complications in Influenza. Notes on the Epidemic in the U. S. Marine Hospital, Stapleton, N. Y.—Z. I. Sabshin draws attention to the fact that close bedside study of cases of influenza shows one general feature, namely, that the circulatory system is the primary seat of complications, in some form or other. This is true during the acute stages and in the course of convalescence; furthermore, patients complaining of some circulatory disturbance frequently give a history of recent influenza. The greatest mortality of the epidemic has been due to acute cardiac or general circulatory complications, the other phenomena, including pneumonia, being in reality secondary. During the acute stage we find: slow pulse, compara-

tively low blood pressure, arrhythmias, murmurs, diffuse apex beat, feeble cardiac sounds, pain over the precordium, associated with cold extremities, sweating and dilated pupils. During convalescence and frequently long thereafter there are feeble cardiac sounds, diffuse apex beat, irregular variations in the pulse rate, stenocardia, shortness of breath, and general signs of neurocirculatory asthenia. Such signs point to vasomotor paralysis and an abnormal condition of the heart muscle. Sabshin has observed the effect of atropine on the pulse rate of convalescents, and in no case was there increase in this rate, and he concludes therefore, that the slow pulse in the influenza convalescent is probably due to changes in the cardiac muscle itself. Clinical observations all point to a damaged or deranged circulatory apparatus, the degree of disturbance varying directly with the intensity of the acute course of the influenza. The author believes that the improvement of the pulse and general condition of the patient occurring with the crisis in pneumonias is due not to a sudden local change in the anatomy of the lungs but to some change in the nervous control of the circulatory mechanism, and that the rapid fatal cases are not due to local anatomical findings but to primary circulatory failure, to which pulmonary changes are but secondary. Congestion is a striking clinical feature and becomes a chronic factor in many cases, a cause of suffering to the patient and a diagnostic puzzle to the doctor. This congestion is of an active rather than passive nature. Its early appearance in all mucous linings, and in the form of bubbling and crackling râles in the lungs, which last long after the acute stage is over, with no swellings or edemas anywhere else in the body, is in favor of its active origin, rather than as a result of myocardial inefficiency. In such cases the physical findings are suggestive of tuberculosis, but the tubercle bacillus is not found in the sputum. Pleuritic, and sometimes pericardial, adhesions are shown by the *x*-ray. Sabshin gives the rationale and order of events as a vasomotor paralysis, local or central, an active congestion, a toxic hemorrhagic edema, a rapid process of destruction, with threatening of perforation of the viscus, in which case nature tries to protect itself by fibrinous exudates, thereby forming adhesions. This results in protracted recovery and in delay in clearing of the lungs, the cough, expectoration, and pus formation, simulating and predisposing to tuberculosis. With the fall or reduction in the general arterial blood pressure, resulting from vasomotor depression, there is diminished renal circulation and reduction of urinary output. Albuminuria is common. Postmortem examination usually reveals congestion of the kidneys. In regard to treatment, Sabshin points out atropine given hypodermically in doses of 1/100 grain to one seventy-fifth grain every three to four hours postpones, if it does not prevent, a pulmonary edema in many cases. Strychnine seemed to keep up the blood pressure and was used with digitalin. Morphine and codeine gave comfort. Hot applications were found to give more satisfaction than cold ones. Summarizing his observations, this author states that the patients observed were all males of more than 18 years of age, mostly sailors. He is inclined toward the following conclusions: (1) Influenza is a toxemia of various degrees, with special localization in the circulatory mechanism. (2) In the malignant cases there is a primary paralysis of the vasomotor system, resulting in congestion and hemorrhages internally and externally throughout all parts of the body. (3) Complete recovery from the toxic and protracted febrile course is doubtful, as the congestion favors secondary infections, adhesions, and chronic cardiocirculatory disturbance. (4) Influenza is to be added to the classical list of diseases affecting the heart. (5) The entire circulatory apparatus being deranged, the therapeutic indication is to improve the circulation by stimulants during the acute stage, support during convalescence, and careful resumption of usual occupation thereafter.

2. Immunization Against Measles.—D. L. Richardson and Hilary Connor report a series of experiments on immunization against measles, which though too few to be conclusive, are sufficiently suggestive to warrant further investigation. Six children were definitely exposed to measles and were apparently protected from the disease by immune serum; one, used as a control, developed measles. Eight others were partially exposed and did not develop the disease after immunization. Three other patients received virus inoculation and immune serum simultaneously. In two there was no reaction. In the third there was a slight reaction indicated by a transient rise in temperature and an atypical rash. The blood serum was prepared as follows: Blood was withdrawn from veins on the flexor surface of the elbow. It was collected in sterile test tubes marked with the name of the patient. These test tubes were placed in the refrigerator over night. Next morning the serum was decanted into one or more sterile test tubes, the serum of each patient being kept separate and a Wassermann test was made of each. Serums of different patients, reacting negatively, were then mixed for treatment. Record was kept of the time after the date of the rash when patients were bled. The serum was kept in the ice-box for a week without preservative, but if kept longer than that a 0.25 per cent. solution of tricresol was added. Serum was given intramuscularly, into the thigh, usually as a single dose within a few days of exposure. Dosage was from 7 to 25 c.c. No reactions, either local or general, were noted. Virus inoculation was carried out as follows: the virus was collected on cotton swabs from the nose of patient twenty-four hours before the appearance of the rash, and the swabs rubbed gently over the nasal mucosa of the infants it was desired to inoculate.

4. Rat-Bite Fever: Two Cases Treated with Apparent Success with a Single Dose of Novarsenobenzol Intravenously.—R. V. Solly describes two cases of rat-bite fever, in both of which there was a history of having been bitten by a rat. In each case the intravenous injection of 0.45 grain of novarsenobenzol was followed by a fall in temperature, which remained normal for one month. There was then a slight rise in temperature which lasted in one case for about a week. Since then both patients have been well. No spirochetes were found in either case. A peculiar body, suggestive of the *Spirochaeta icterohaemorrhagica* was observed in one case, and it is suggested that this might have been a couple of spirochetes adhering to a red cell. In the second case, in one culture tube, a bacillus having

the cultural characters of the *B. coli communis* was found, but this was probably a contamination. The author remarks that many diseases other than syphilis might be successfully treated by salvarsan and its substitutes.

5. Prophylactic Treatment of Constipation in Children.—Vynne Borland draws attention to the importance of constipation in children, since it affects so markedly the child's health in later years. It is necessary that the term "constipation" should be correctly understood: it means that, for some reason, the rate of expulsion of the bowel contents and the amount expelled are below normal. The characters of a normal stool must also be understood. In the prevention of constipation, satisfactory hygiene in the home is of paramount importance—abundant fresh air and sunlight during the day, and a fresh, airy room at night, the position of the child in the cot being changed at intervals. Regular periods should be reserved for exercise, according to the child's age. Feeding times should be at definite hours, the child being wakened if necessary. The longer the interval between feeds the better. The author has found that many cases do well on four-hourly feeds; others require five or six feeds per day. In no case should the child be fed during the night, and the essential point is regularity. The bath should be given at the same time every morning and the child trained into the habit of a morning stool after the bath feed. If a laxative is required a dose of syrup of figs may be given at night. Liquid paraffin is the best lubricant. If the bowels have not moved in the preceding 24 hours, a warm normal saline enema, 1 dram to an ounce, is best; large enemas produce distension and loss of tone. If soap is used, a mild superfatted soap should be chosen, since ordinary soap tends to set up catarrh and proctitis, and consequently constipation. Neither method should be pushed for any length of time, as impairment of the normal rectal reflex would result. A binder should not be used after the navel has healed; it prevents proper development of the muscles of the back and abdomen, and when round the abdomen constricts the bowel contents, and, if it is loose and slips up, it prevents proper development of the chest. It is important that the expectant mother should regulate her bowels. Small doses of laxatives should be taken at night to insure the morning stool rather than larger doses once or twice a week. Borland points out the danger of giving castor oil to the baby, such a procedure being frequently the starting point of constipation. He says: Never give castor oil unless there is diarrhea. A child should gain from 4 to 7 ounces per week. Underfeeding is evidenced by a small and insufficient stool. It is better to give small quantities of milk after each feed than to replace one or two feeds by a bottle-feed, as the natural stimulus of sucking is thus not interfered with. Insufficient fat is liable to produce constipation; on the other hand, too much fat is to be avoided, and if the stools become pasty and greasy the quantity should be reduced. In case of faulty fat digestion some pancreatic extract should be given. Curds in the stool should be examined to see if they consist of undigested milk or small rolls of dried mucus; if the former, humanized or citrated milk, should be given, and in case of the latter liquid paraffin is indicated. If the stools are too dry the feed should be further lubricated or the child given sips of water between feeds, the water always being first boiled. Too much water must also be avoided, since the bowel becomes lazy if stools are always watery. A little fruit juice each day is of benefit. After an attack of acute diarrhea, the tone of the bowel must be restored and if simple hygienic measures do not suffice, a mixture of cascara, nux vomica, and liquid paraffin may be given. Mothers should be warned of the danger of the indiscriminate use of soap suppositories as if this remedy is resorted to too frequently the natural stimulus of rectal reflex is lost. In constipation in mental defectives, cretins and in cases of infantilism, the administration of thyroid extract is of benefit.

1. The Etiology of Influenza.—A Filtrable Virus as the Cause with Some Notes on the Culture of the Virus by Noguchi's Method.—The late Major H. Graeme Gibson, Major F. B. Bowman, and Captain J. I. Connor report the results of an attempt to cultivate the "filtrable virus" of influenza and experiments in the transmission of the disease to animals by inoculation with the cultures so obtained. The animals used were babboons, *Macacus rhesus* monkeys, rabbits, guinea pigs, and mice, and in all these animals they succeeded in producing, by the inoculation of both filtered and unfiltered sputum, lesions that appear similar to those seen in human cases of influenza. For experiments with blood transmission they used *M. rhesus* monkeys and mice. The results in the case of the two monkeys inoculated were not wholly satisfactory, but experiments with mice gave a high percentage of positive results, and the authors believe it is possible to transmit the virus by means of infected blood to the latter animals. In the case of the mice the dose given per body weight was much larger than the monkeys received, and this factor no doubt played a part in the results obtained. With cultures it was found possible, by Noguchi's method, to infect monkeys, rabbits, guinea pigs and mice. (The authors give a careful description of the method they employed in the preparation of the Noguchi culture tubes and of their staining methods). Although they consider their experiments too small in number to justify the drawing of final conclusions, they have made the following deductions from their work: (1) The apparent immunity of some animals to filter-passing viruses and the occasional difficulty of the transmission of these viruses by means of blood is well known. When this is taken into account the number of positive results obtained would seem to be significant. (2) The pathological lesions in what may be called experimental influenza in animals closely resemble those seen in the lungs of men. (3) There is some evidence in favor of the view that the passage of the virus from one animal to another may raise its virulence. (4) Inoculation of the filtered and unfiltered sputum taken from cases of influenza, especially at an early stage of the disease, has been found to produce lesions in the lungs in a high proportion of inoculated animals. The inoculation of blood may not always produce such striking results. (5) A minute microorganism of a coccoid shape may be grown by Noguchi's cultural methods from: (*a*) The kidney of infected animals; (*b*) the filtrates of lung tissue, and (*c*) the filtered sputum from cases of influenza. The cultures have been carried by us to the third generation by direct culture. The cultures when inoculated into animals produce typical "experimental influenzal" lesions, and cultures can be recovered again from the animals so inoculated. (6) In view of these findings we consider that there are very strong grounds for considering that (*a*) The organism isolated by us is capable of passing through a filter. (*b*) That it is in all probability the cause of influenza as seen to-day. A similar organism, having the same properties, has been described by Captain J. A. Wilson, R.A.M.C. (see MEDICAL RECORD, March 8, 1919, p. 420), and this observer and the authors are of opinion that the organism isolated independently is the same in both cases. A note is added to this paper by Colonel S. L. Cummins on the regrettable death of Major Gibson. Major Gibson succumbed to an attack of influenza before he had an opportunity to revise or even complete the summary of his work.

2. Symptoms of Hyperthyroidism Observed in Exhausted Soldiers.—Major W. Johnson draws attention to (a) The occurrence of a definite condition of exophthalmos in exhausted soldiers; (b) The fact that this exophthalmos is present in the early stage of advanced conditions of exhaustion, and that it is only temporary,

lasting usually two or three weeks. (c) When it disappears the patient at once merges into the group of cases labelled "neurasthenia," and is indistinguishable from them. He therefore puts forth the following hypothesis: (1) That a large number of so-called psychoneuroses are cases in which the symptoms are due to a state of disordered internal secretion the result largely of emotional exhaustion, and, to a less degree, of physical exhaustion. (2) That many cases which are later diagnosed irritable heart, D. A. H., soldier's heart, and neurasthenia, are really cases of this class, and that possibly many have passed through a slight state of exophthalmos without its importance being realized. The author suggests that all such cases should be classed under a suitable term, such as *Exhaustion syndrome*. He points out that this term would have the advantage of not suggesting a period of chronic invalidism such as a soldier associates with D. A. H., neurasthenia, and similar terms. He adds that having observed some thousands of cases of breakdown in the line—in men otherwise healthy—he has become impressed by the fundamental unity of the group, and by the fact that exhaustion is the active etiological factor.

1. Vaccine Therapy, the Most Rational and Effective Method of Treating Whooping Cough. Charles James Bloom.
2. The Use of Vegetable Milk in Children. Preliminary Report. Henry Dwight Chapin.
3. The Complement Fixation Test for Tuberculosis In Infancy and Childhood. Henry Heiman.
4. Report of the Cornell Nutrition Class. May G. Wilson.

1. Vaccine Therapy, the Most Rational and Effective Method of Treating Whooping Cough.—Charles James Bloom says that he has been interested in vaccine therapy for whooping cough since 1912, and though at the start, with small doses, discouraging results were his lot, he continued the treatment, until now he feels that his conclusions are convincing and thorough. In 1916, and again in 1917, Bloom brought to the attention of the New Orleans Parish Medical Society the success he had had with the method of treating whooping cough, and through his efforts a great many physicians are using it in New Orleans. Statistics from New Orleans show that whooping cough is a fatal disease. The death rate from whooping cough during the past five years has been 2 per cent. greater than diphtheria; 7 per cent. greater than measles, and 6 per cent. greater than scarlatina. Ordinarily without the vaccine treatment the duration of pertussis, according to authorities, last: Holt, 60 days; Rotch, 90 days; Cantley, 120 days; Garrod, Batten and Thursfield, 40-148 days, and Ruhrah, 90-180 days, respectively. The total average and duration of Bloom's entire series was about 20 days. The question of the cough is a valuable one. In no two cases are the results found the same. But there is, as a rule, a difference in the intensity and number of coughing spells following the administration of the vaccine. Some cases seem to "clear up" after the first or second injection; others continue throughout the duration of the disease, but the cough is trivial and does not provoke vomiting, and is not associated with cyanosis. Bloom has not seen in the past four years a case where treatment was instituted right from the first few days of the catarrhal stage that did not obviate the cyanosis entirely or render less severe the intensity of the individual coughing attacks. One will see rather marked improvement as far as the number of coughing spells, or the intensity is concerned, as soon as two or three injections have been given, although on the night following the administration of vaccine the cough is considerably increased. Several cases referred to Bloom in the second stage, where the symptoms of cyanosis are paramount, cases that seem to cease to breathe each time they cough, the effects of the vaccine in some of the cases have been almost instant, while in other cases the number of attacks were deferred to longer intervals. Summary and conclusions as to treatment are as follows: 1. No active case of whooping cough has developed in a single instance where the prophylactic administration of the vaccine had been given. 2. A number of cases thus vaccinated have been directly exposed to whooping cough since the vaccine was given them. During the past three years the writer has used both the simple and combined or mixed vaccines in about 300 cases. Constant and quicker results have been obtained when the combined vaccine was used. Unfortunately autogenous vaccines are not practical for many reasons, namely: (1) In the early stage, when the vaccines are needed most, there is practically no expectoration. (2) In only rare cases is any sputum whatsoever secured; hence the inability to culture the organism. (3) Seldom can a pure culture be secured. (4) By the time the vaccine is delivered the second stage will have been started. From the very onset of this important subject, when the vaccines were first used, the writer has felt that perhaps there were two bacteriological factors: one the specific organism, and the other the influenza bacillus. The belief prompted his deliberate use of a mixed vaccine from the very start, contrary to the arguments of others. In his successive combinations the number of Bordet-Gengou bacilli and influenza bacilli, constituting the vaccine used, have been increased in numbers. In the future, in some of my cases, a vaccine containing these two organisms alone will be tried. Mallory has found two organisms in the dog. The question of injections and time concerns the individual case, and no definite rule can be ascribed to either interrogatives. The loss of appetite, loss of sleep and restlessness, while present in the majority of cases, were not of sufficient importance to alter methods, and had no relation whatsoever, directly or indirectly, with the vaccine therapy. As far as complications were concerned, the writer has yet to note a single case of pneumonia, tuberculosis, etc., in the cases recorded by him. In relation to reaction, it is noted that following the hypodermic administrations, the temperature rarely exceeds 101° Fahr., the temperature is not affected in the greater proportion of the cases. As a matter of fact, the only evidence of the aftermath is a "hardened knot" described by mothers at the site of the injection. Bloom has never noted a case of anaphylaxis. His final conclusions are that (1) vaccine therapy in pertussis is rational and effective; (2) experience has proven its efficacy, both as a prophylactic, and as an active therapeutic agent. (3) Usage (*a*) Minimizes loss of weight; (*b*) Reduces the duration of the disease; (*c*) Decreases the intensity of the illness; (*d*) Foreshadows the possibilities of complications and sequelae; (*e*) Unattended by danger of anaphylaxis, etc. (*f*) Limits the mortality.

4. A New Technique for Suspension of the Kidney. R. W. Penick.

4. A New Technique for Suspension of the Kidney.—R. W. Penick points out that it is well to bear in mind that in practically every case of movable kidney the abdominal walls are found very lax, demonstrating the very important part they play in supporting the normally placed organs, and the after treatment should take care of this condition following nephropexy. An interesting and rather remarkable fact has been the recovery or improvement in a number of cases operated on by English surgeons of movable kidney associated with insanity. Suckling reports twenty-one cases in which insanity disappeared after fixation of the kidney, and Billington reports most encouraging results obtained in the same manner. The technique in detail is as follows: Penick uses the Kelly incision, approaching the kidney through the superior lumbar trigonum, only he makes the incision a little larger, if necessary. When the deep lumbar fascia is reached it is opened with a clean cut, and beginning at the lower angle of the wound, a ribbon of fascia is dissected about two-thirds of an inch wide. The end is secured with a hemostat and laid aside for the present, and the operator proceeds to deliver the kidney up into the wound as usual.

The perineal fat is stripped to the hilum and the capsule incised and dissected, the sutures introduced two on each side. These sutures are caught in hemostats and laid aside, while the perineal fat is gathered by a circumferential large suture, forming a cup-shaped support under the kidney, and the ends are left long for later attachment at the lower angle of the wound in the musculature. The ribbon of fascia is now picked up, and a large chromic gut suture threaded into the end to prolong it; it is then fitted around the lower pole of the kidney, just below the hilum, and a stitch securing it to the capsule of the kidney near the front is introduced to prevent slipping. The ends of the suture prolonging the ribbon of the fascia are left in the hemostat while the kidney is being replaced, and the sutures of the capsule are secured in the adjacent musculature, as usual in this procedure. When this stage is reached the kidney is placed in the position desired and the suture prolonging the ribbon of fascia threaded on a carrier or large needle and fixed in the muscles of the back, at the most convenient point, fitting snugly around the kidney and holding it securely while the denuded surface on the kidney forms adhesions. The large sutures in the subphrenic fat securing a support under the kidney are now drawn sufficiently taut, forming a cup-shaped support. The last procedure closes the loose space under the kidney, and while it may not be necessary, it is quickly and easily done; indeed, Dr. Bartlett uses this principle alone, almost, in dealing with this type of kidney surgery. The wound is then closed in the usual way, layer by layer. The conclusions are as follows: (1) The use of fascia seems logical, gives the greatest security under the severest postoperation strain, and prevents tilting, rotation, and sagging. (2) It is easily and rapidly done. (3) Good surgery demands that we employ methods that insure the greatest security, and this technique seems to give us that security. (4) It is reasonable to suppose that this fascial band eventually forms a stable ligamentous support that would hold the kidney in place in the absence of any other support.

Berliner klinische Wochenschrift.

February 10, 1919.

Researches on the Elimination of Quinine.—E. Küster and H. Wolff have studied the elimination of this drug in patients who had been taking it for a considerable time. Some writers have maintained the rate of elimination varies with the degree of acquired immunity to the drug, which depends upon a greater destruction of quinine in the organism, this destruction being in direct ratio to the acquired immunity. The writers' conclusions are not in accord with the above propositions, because they note that subjects accustomed to the use of quinine eliminate it in the same way as those unaccustomed to its use; that immunity to quinine is rather more due to the malarial plasmodium than to the patient himself.

Nutrition During the War.—F. W. Bach refers to the usefulness that may lie in studying the metabolism during the present scarcity of food and to establish the minimum absolutely necessary for maintaining the normal weight. His researches in this direction consisted in making dosages of the nitrogen in the total urine, the figures obtained being multiplied by 6.25, this representing the amount of albumin utilized by the organism. The procedure is evidently only an approximate one, because both the feces and sweat contain a portion of the total nitrogen, but these sources of error are of only secondary importance and do not influence the appreciation of the results. The mean figures found by the writer are: A subject weighing 61 kilograms has a daily elimination of nitrogen of 8.917 grams, therefore 56.17 grams of disintegrated albumin. These figures were obtained in subjects who had lost considerable weight from insufficient food during the war and who offered at the time the calculations were made a stationary weight.

Renal Changes in Dysentery.—E. Wolf shows that these changes consist in a diffuse nature in the glomeruli with marked changes in the canaliculi, in the form of hyalin, fatty and necrobiotic processes. These morbid phenomena can be regarded as primary localizations in the vessels of the pathogenic agent. In point of fact, the vessels offer by the fifteenth day of the disease (if renal manifestations arise) a dilation with thromboses and nuclear degeneration in the walls, occasionally with a leucocytic infiltration. The cases reported by the writer did not offer any apparent clinical manifestations.

Münchener medizinische Wochenschrift.

February 7, 1919.

The Agglutinative Power of the Weil-Felix Bacillus.—F. Schiff has studied the influence of the sugar content in culture media on the biologic properties of the bacillus X 19, from the viewpoint of serologic diagnosis of typhus fever. The writer offers the following conclusions: (1) An absence or decrease of agglutination of this bacillus may be due to an insufficient quantity of sugar in the broth. Bacilli grown on sugar free agar-agar are not agglutinated by sera. With increasing amounts of sugar the rapidity of the reaction likewise increases, as well as the amount of precipitation. (2) When the sugar content is too great, cultures in series on over-sugared broths end in spontaneous agglutination. (3) Emulsions of bacilli which have lost their power of agglutination by heating at 56° C., recover it after washing in a normal salt solution. (4) Cultures heated at 100° C. for two minutes usually retain the power of agglutination, in which case this power depends upon the nature of the culture medium, and does not always correspond to the power of agglutination of the living bacillus. Therefore, emulsions which are to be used for diagnostic purposes should be selected from tested stock cultures. (5) The sugar content of broth influences the emulsions of the bacilli heated at 100° C. in the same way that it does living bacilli. Cultures grown on sugar-free broth are not capable of agglutination while living, but become specifically agglutinable after being killed. (6) Cultures which have lost their power of agglutination from growth on Drigalski's medium and endo-agar do not recuperate their power of agglutination either by heating or inoculation on neutral agar containing sugar. The writer has been able to note that other bacilli (Eberth, paratyphoid A, and cholera) change in their power of agglutination by a given specific serum, according to the amount of sugar contained in the culture medium.

Wiener medizinische Wochenschrift.

February 8, 1919.

Voluntary Provocation of Psychoses.—A. Pilez has twice met with instances of provoked acute psychoses induced by the subjects in order to escape military service. In the first case the subject resorted to a potion that popular tradition in his country (he was a Tchec) regarded as a producer of insanity. Analysis showed that this potion was composed of a mixture of belladonna and daphne leaves. The patient presented marked delirium, psychomotor agitation and dilatation of the pupils. This condition was, of course, only transitory, and ended in recovery. The second case was that of a man who had formerly taken sodium salicylate, which had given rise to an acute delirium. Knowing this, the soldier in question took sodium salicylate, which again produced an acute psychic paroxysm, and for a time was mistaken for a state of dementia.

War Neuroses.—M. Kahane offers some general remarks on this subject which are lacking in interest, but besides these the writer advises a procedure of objective examination which, according to him, may reveal a predisposition to neuroses. This consists in galvanopalpation. A weak current from an anode (for example, 0.3 milliamperes) is passed over the cutaneous surface and may give rise to vasodilatation which, when it occurs, denotes a vasomotor lability peculiar to psychoneuroses. The procedure has only a positive value, since vasomotor lability only indicates the reality of a neurosis, while a negative reaction should not lead one to conclude as a matter of course that there is simulation.

The Use of Barany's Drum and Reflex Winking in the Diagnosis of Simulated Deafness.—E. Wodak states

that this procedure is not a sure one. The reflex may be produced from the perception of the aërial vibrations by the trigeminus, even in the case of true deafness. It may also be absent when there is perfect integrity of the auditory apparatus.

La Presse Médicale.

March 10, 1919.

Pityriasis Rosea Is a Tuberculide.—Le Damany, after a prolonged study and follow up of cases of this apparently insignificant dermatosis concludes that it is a manifestation of tuberculosis. This is shown by the positive tuberculine reaction in men of apparently robust health, the frequent association of other manifestations of the disease as micropolyadenopathy, the tendency to recurrence, etc. Originally the affection was regarded as a form of ringworm until Brocque disproved this possibility. Sabouraud placed it among the erythemas of central origin, due to some unknown agency, and Gougerot attempted to show that it rested on some constitutional disorder. These views naturally culminate in the author's theory of paratuberculosis. The general belief that there is but a single outbreak in a lifetime suggested acquired immunity to some noxious principle, but long control of the patients has shown that relapses are possible. They may follow the first so promptly as to suggest an ordinary relapse of a primary acute manifestation, or may not reappear for several years. The malady appears to be largely a disease of the robust like psoriasis. It runs its course in from one to two months. Its incidence is unknown because of its benign character. The almost constantly present polyadenopathy is strongly suggestive of a tuberculous factor, however benign. Aside from this, it has been seen in association with lichen scrofulosus, scrofulous lymphnodes, pulmonary tuberculosis, suspicious apices, tuberculous family history. The tuberculin reaction has already been mentioned. Numerous illustrative cases are appended, from which we select one. An adjutant was seen with a well-marked case of pityriasis rosea, involving the entire surface. The general condition was excellent. In the axillae micropolyadenopathy. The eruption vanished in about ten weeks. Examination for tuberculous lesions of the classical types was negative. A retraction of the sheaths of the flexors of the palms, suggesting a beginning Dupuytren's disease, is worthy of mention because the claim is heard in some quarters that this lesion is paratuberculous. The cutireaction made 25 days after the first outbreak was frankly positive.

Correspondenz-Blatt für Schweizer Aertze.

February 22, 1919.

Influenza Heart.—Eichhorst refers to the numerous reports of influenza death from vasomotor paralysis and the attempt to control this condition with adrenaline. The vasomotor theory has been based on the coincidence of pallor and weak pulse with but slight involvement of the lungs, intact heart and overfilled splanchnic vessels. The author has no quarrel with this theory and has even had excellent results in such cases from the use of adrenaline. He only would add that the heart in these cases may be damaged. At autopsy he has found but little anatomical alteration in this organ. The number of grippe patients treated by him to January 1 was 2,411, with a mortality of 14 per cent. Without exception the 351 deceased showed some pneumonia, usually bilateral, and confined to the bases. But 6 cases of mitral endocarditis were found, and the total number with anatomical changes was but 14. Hence such a term as influenza heart must be a clinical one only. The author has noted tachy and bradycardia, extrasystole, and cardiac neuralgia. The first named is extremely rare, but 4 cases being noted. Bradycardia was far more common and occurred both in the febrile period and in convalescence. A pulse of from 48 to 60, with a temperature of 40° C. was followed by a rise at defervescence in some cases. The postinfluenzal type may persist over long periods. Extrasystole was likewise seen at the acme of the fever and in convalescence, while cardiac neuralgia was very rare. The four types of cardiac troubles, when considered jointly, appear to represent a definite condition, influenza heart, which appears under different modalities, but is genetically perhaps one and the same affection. The double incidence at the height of fever and at defervescence (the same patient apparently does not show both of the incidences) seems common to all and no cardiac death has been associated with this clinical behavior.

Revista Medico-Cirugica do Brazil.

October, 1918.

Influenza in Brazil.—The entire issue of this number is taken up with this subject. Dr. Carl Seidl, the editor, former director of public health, relates that the grippe reached Brazil from Dakar in French Senegal on October 3. The epidemic had exploded at Dakar on September 10, and on the 26th the Brazilians were warned by cable that cases of Spanish influenza were on board a Dakar steamer of the "Royal Transport" line. Up to this time the local health officers had not known the nature of the new African disease, and believed it either cholera or bubonic plague. Seidl was at the time the director of public health, and seems to have been blamed for the spread of the pandemic in Rio. Having resigned from this post, he gives a minute account of his stewardship in the matter and in addition showed that in other great cities the health officers had been powerless to prevent the invasion of the pandemic. He was later exonerated by the responsible authorities, and some of his colleagues who had at first by their silence apparently endorsed the attitude of the public as reflected by the daily press, made a tardy reparation. A document is reproduced which shows that as early as September 22 Seidl had warned the public of the presence of influenza in Spanish, Portuguese, and African ports, and the certainty of a visitation in Brazil. At that time there were no suspects in Rio, and the death rate in July and August showed that no marked disease was sending up the mortality. There appears to have been one scare in connection with a passenger steamer which was held up for a period of quarantine, but five deaths which occurred on this boat could not be recognized positively as influenza. In the preceding pandemic Brazil appears to have escaped a severe visitation (it must be remembered that while scarlatina is not only rare but benign in Brazil, the year 1842 saw it appear in an epidemic and deadly form). In another article the author goes more fully into the case of the quarantined steamer. It was a British vessel with over 500 third class passengers, which after having been en route from Liverpool for 35 days, reached Brazil on September 14. On its voyage it had stopped at Lisbon Recifa, and Bahia. As stated, five people died on board with alleged influenza. One woman passenger died later in hospital of the same malady. The diagnosis of Spanish influenza in connection with these cases seems to have been in dispute, and in any case the malady did not enter the country in this manner. Granting that the visitation is inevitable, sooner or later, it is of course easy to criticize the health office for lack of hospital facilities and for refraining to employ certain prophylactic measures of doubtful utility.

Recent Graduation Theses of the University of Bordeaux.—As is most natural, a state of war reacts upon the undergraduate who is obliged to serve in the army and leads often to the preparation of a medical graduation thesis on a military subject. In a series of theses by recent medical graduates reviewed in the *Journal de Médecine de Bordeaux* for January 15 we find the following devoted strictly to military subjects: Nervous crises in soldiers who have sustained cranial cerebral injuries (epilepsy, hysteria, and hybrid states); secondary hemorrhages in war wounds; pneumonia in negro soldiers and its treatment; lesions of the eyeball due to warfare; immediate treatment of projectile wounds, etc. By way of contrast we may add theses on non-military subjects: Ergography by Mosso's method; hematology of diphtheria; nasopharyngeal polyp; nonsuppurative mastitis in infectious diseases, etc.

Book Reviews.

THE ORGANS OF INTERNAL SECRETION, THEIR DISEASES AND THERAPEUTIC APPLICATION. A Book for General Practitioners. By IVO GEIKIE COBB, M.D., M.R.C.S., Neurologist, Brinnington Section, Second Western General Hospital. Second Edition. Price, $2.50. New York: William Wood and Co., 1919.

THIS is a revised and enlarged edition of the work which appeared first about two years ago. It is founded on a series of articles which appeared in medical journals and aims merely to be a guide in the use of the preparations of the organs of internal secretion in the treatment of their disorders. As such it will be found very helpful and, while some of the statements seem at first sight to be rather overenthusiastic, nevertheless it is necessary to defer to the author's experience. He naturally devotes the largest space to the thyroid gland, and about one-half of the book is taken up with the thyroid, adrenal and pituitary glands. The rest of the endocrine glands are still as much of a mystery as ever, apparently, but it is possible to employ them tentatively and to hope for good results. Every practitioner meets numerous patients who should benefit by some internal secretion therapy, if he only knew what to give. This book should help him to choose the preparation and to regulate the treatment.

A TEXT-BOOK OF PHYSIOLOGY FOR MEDICAL STUDENTS AND PHYSICIANS. By WILLIAM H. HOWELL, Ph. D., M.D., Sc.D., LL.D., Professor of Physiology in the Johns Hopkins University, Baltimore. Seventh Edition. Thoroughly Revised. Price, $5.00. Philadelphia and London: W. B. Saunders Co., 1918.

THE successive editions of this standard work appear so rapidly and the revisions are kept so thoroughly up to date that a cursory glance at any two successive editions shows but few changes. But there are numerous small changes, sometimes additions, sometimes omissions, often alterations—all tending to keep this book in the front rank of text-books on physiology. The author has managed to make this new edition very little larger than its immediate predecessor, and it is less than forty pages larger than the fifth edition.

CLINICAL MICROSCOPY AND CHEMISTRY. By F. A. MCJUNKIN, M.A., M.D., Professor of Pathology in the Marquette University School of Medicine. Price, $3.50. Philadelphia and London: W. B. Saunders Company, 1919.

THIS volume is based on a course given to students and has been prepared from the laboratory rather than from the clinical standpoint. To this end clinical descriptions are omitted. To increase the practicality of the work "only those methods are included which have a definite and practical use." The chapters on blood cytology and upon histological and autopsy technique are easily the best in the book and it is apparent that it is with these subjects that the author is most familiar. In other portions of the work there is often little system in the presentation of the material, and it is sometimes difficult to sympathize with the author's choice of methods for presentation. For instance, he includes a very imperfect description of the Abderhalden test and wholly omits any mention of the fractional test meal. On the whole, while the ground covered is extensive, the book is better suited as a note book in a course presenting adequate didactic lectures and practical work than as a source of information to the questioning practitioner.

SPEECH TRAINING FOR CHILDREN. The Hygiene of Speech. By MARGARET GRAY BLANTON and SMILEY BLANTON, B.S., M.D., Captain Neuro-Psychiatric Unit, Medical Corps, U. S. Army; Associate Professor, University of Wisconsin. New York: The Century Company, 1919.

TRAINING in the development of speech in children is important, as clear enunciation means much in these days. In the past, and perhaps especially in this country, that branch of education concerned with training in speech has been sadly neglected and the results are to be observed on every side. Not only should enunciation be distinct, but the voice should be trained so that the tones are soft and modulated and do not offend the ear by their harshness. The authors explain in this book how the object may be best attained, and it may be recommended to the earnest consideration of the medical profession and public.

AMERICAN RED CROSS TEXT-BOOK ON FIRST AID: WOMAN'S EDITION. A Manual of Instruction. By Colonel CHARLES LYNCH, Medical Corps, United States Army. Prepared and Endorsed by the American Red Cross. Second Edition, with 31 Plates, Containing 92 Figures. Philadelphia: P. Blakiston's Son & Co.

IT was peculiarly appropriate that a woman's edition of a manual on first aid should have been written and published. The issue of the first edition for women showed that it was needed. This edition has been revised and brought into line with recent medical and surgical progress. Its value can hardly be overestimated.

AMERICAN RED CROSS TEXT-BOOK ON HOME HYGIENE AND CARE OF THE SICK. By JANE A. DELANO, R.N., Chairman of the National Committee, Red Cross Nursing Service; Director, Department of Nursing, American Red Cross; Late Superintendent of the Nurse Corps, U. S. A.; of the Training School for Nurses, Bellevue Hospital, New York City, and of the Training School for Nurses, Hospital of the University of Pennsylvania. Revised and Rewritten by ANNE HEWEY STRONG, R.N., Professor of Public Health Nursing, Simmons College, Boston. Second Edition of the American Red Cross Text-Book in Elementary Hygiene and Home Care of the Sick. By JANE A. DELANO and ISABEL MCISAAC. Prepared for and Endorsed by the American Red Cross. Price, 60 cents. Philadelphia: P. Blakiston's Son & Co., 1918.

IT is a truism now that hygiene, and especially domestic hygiene, is one of, if not the most, important branch of preventive medicine. Most contagious and infectious disease can be prevented from spreading if the mother of a family knows the elementary laws of hygiene and how to put them into practice. This book was written and this second edition was rewritten and revised with this aim always in view. The authoress has fully succeeded in giving to the public a manual on home hygiene which gives all the essential methods by which to care for the sick and safeguard the remainder of the family and which is couched in expressive but easily intelligible language.

AMERICAN RED CROSS ABRIDGED TEXT-BOOK ON FIRST AID. General Edition. A Manual of Instruction. By Colonel CHARLES LYNCH, Medical Corps, United States Army. Prepared and Endorsed by the American Red Cross. Second Edition. With 41 Illustrations. Price, 35 cents. Philadelphia: P. Blakiston's Son & Co., 1919.

THIS is an abridged edition of the American Red Cross Text-Book on First Aid and Relief Columns. It is also a second edition and has been revised and brought up to date. It is clearly written in concise language and adequately fulfills its avowed purpose.

ROENTGENOTHERAPY. By ALBERT FRANKLIN TYLER, B.Sc., M.D., Professor of Clinical Roentgenology, John A. Creighton Medical College; Attending Roentgenologist, St. Joseph's Hospital, Bishop Clarkson Memorial Hospital, Ford Hospital, Immanuel Hospital, Douglas County Hospital, and Lord Lister Hospital, Omaha, Neb.; Member American Roentgen Ray Society; Fellow American Medical Association, etc. With 111 Illustrations. Price, $2.50. St. Louis: C. V. Mosby Company, 1918.

THIS is a book on Roentgen therapy designed to set forth the principles of the treatment in such easily comprehensible terms that the beginner can understand. Description of the apparatus is given and a feature of the work is the number of illustrations, which serve to interpret and exemplify the text. The book is eminently suitable for those desiring instruction in Roentgen therapy.

Society Reports.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting Wednesday, March 5, 1919.

THE PRESIDENT, COLONEL WILLIAM J. TAYLOR, IN THE CHAIR.

Observations on Otolaryngology in the War. — Dr. HARRIS P. MOSHER, Lt. Col., Medical Corps, U. S. A., presented this paper, which began with a few pessimistic paragraphs on "personnel." Then took up the two special hospitals and described a day at Cape May. After this it dealt with oral and plastic surgery, a subject overlapping otolaryngology as practised by many. Fully half of his observations, Col. Mosher said, were assembled in 1915, while he was serving with the British. The paper later considered otolaryngology in the United States, discussing in order the prevailing bacteria of the epidemics, carriers, and the use of dichloramine-T. This discussion was followed by a tabulation of operations, and the paper concluded with a statement of some new clinical observations made in the cantonments, and a brief report on the influenza epidemic from the standpoint of otolaryngology. While the paper was largely made up of "pickings from other men's brains," the author said he had tried in each instance to give due credit. The Division of Surgery of the Head, he said, had established two special hospitals, and the Section of Otolaryngology was, of course, represented in them. The first hospital was at Cape May in this country; the second at Vichy, in France, and was known as No. 115. Before the personnel selected for it arrived the Chateau-Thierry drive had filled its beds with general surgical cases. Major Ivy had reported, however, that in the section on maxillo-facial surgery 305 cases of this character had been treated in the four months ending January 18, 1919. The dentists at Cape May, the author observed, had a unique opportunity to compare the results of the different types of splints put on overseas. This splinting work was, in the writer's opinion, one of the best American contributions to the surgery of the war. He had come away from Cape May feeling very proud that the Division of Surgery of the Head had fathered such an upstanding hospital. The number of special cases which would return from overseas for treatment was roughly estimated as follows: Peripheral nerves, 5000; maxillo-facial, 300; blind, 250 to 300; ear, 300 to 500; cases for instruction in lip-reading, 100. The capacity of the Cape May Hospital was stated to be about 700 beds. Two things which had impressed him profoundly during the war were the dental work and the associated plastic work of the face. Interdental splints, the restoration of the form and function of the jaw by a vulcanite plate which allowed the patient to use his jaw at once and furnished a surface over which defects in the lip or cheek could be repaired, and the use of bone transplants for large losses of substance had supplemented the cruder methods of treatment of four years ago. It had been learned during the war that the loss of a very large amount of bone from the lower jaw could be replaced by Nature. The loss of even as much as an inch of bone at the symphysis would finally be bridged across if the ends of the jaw were immobilized by an interdental splint. Otolaryngologists should acquaint themselves with the possibilities of the mechanical help that the dentist would give the surgeon who did plastic work on the nose and face. Col. Mosher said that at Epernay Col. de Schweinitz and he had found Majitot implanting sheep and lamb cartilage for supports in plastic operations of the face. He kept a supply in a weak solution of formalin. Gillies at Sidcup used human cartilage, keeping it, however, in the novel store house of the abdominal wall. He had exhibited one patient with six pieces implanted in the fat of the abdominal wall. While the methods of using a double skin graft over a Stent's mass, and of burying cartilage and turning down later the flap containing it were not new, the war had brought these procedures into very great prominence. Major Scott and his collaborators, dealing with the causes of mastoiditis, were quoted as saying that by "locality infection" was meant the occurrence in a locality or army post of a certain organism which was found to predominate either singly or combined, in infections occurring in that particular locality or army post. At one camp, for instance, the hemolytic streptococcus might be the organism found in the tonsil crypts, in pneumonia, in mastoiditis, or other diseases, while in another camp the pneumococcus or streptococcus viridans might be the prevailing organism. Any one of these organisms might become virulent for a certain period and then apparently become of little consequence. However, when an epidemic of tonsillitis, measles, scarlet fever or influenza occurred then the particular organism for a certain locality suddenly assumed the rôle of secondary invader and became the predominating factor in complications. That the temporary home for this "locality-infection-organism" is in the tonsil crypt is undoubtedly true, while the accessory nasal sinuses are at times the home of the organism. . . . One must conclude that the occurrence of mastoiditis as seen in army cantonments depends upon the surroundings of the individual and the presence of a virulent organism such as the streptococcus or pneumococcus. Further, that the invasion of the mastoid occurs directly from the naso-pharynx or the blood stream." Colonel Mosher observed that there was something uncanny in the sudden acquisition of great virulence by certain bacteria which had been for a time harmless. Further than the knowledge that overcrowding, fatigue and chilling of the human body are important causative factors in this result, he regarded the process as a mystery. With the solving of this problem preventive medicine would take a great leap forward. The war had brought into startling prominence the long known fact that the throat especially, the nose and its accessory sinuses were the primary lodging places of the bacteria responsible for the infectious diseases and those that are sputum-borne.

Dunham had devised a gang spray for use with troops and demonstrated that a thousand men could be sprayed within an hour. He had showed that the spraying with dichloramine-T markedly reduced the bacterial flora of the nose and throat. From the extended study made in the camps it would seem to the writer to be a good plan in civil life regularly to culture the nose and throat of all hospital personnel and to spray with dichloramine the nose and throat of every patient. Among new clinical observations by the otolaryngologists in the cantonments reference was made to Major Owsley's description of a series of cases of ulcerative laryngitis due to the pneumococcus, distinguished by a superficial ulceration of the anterior ends of the vocal cords, the chief symptoms being hoarseness and aphonia. There had been ready response to treatment with solutions of silver. Major Eagleton had successfully placed a bone graft from the tibia in the cavity of the mastoid process produced by a simple mastoid operation. He felt that he had a new frontal sinus operation, and Major Fetterolf had confessed to a new procedure for the resection of the nasal septum. At one of the base hospitals there had been a number of cases of hysterical aphonia, "Whispering Willies," as they were called, and in the cure of these the psychiatrist had great success. Holmes and Harris had drawn attention to the advantageous use of gas oxygen for producing anesthesia for mastoid operations in pneumonia cases. Porter and Orton had reported similar cases operated under local anesthesia. In thirty-nine mastoid operations at Camp Zachary Taylor in January, five were bilateral. In a retrospective view of the war experiences Colonel Mosher felt it might be said that draft examination should have been more thorough; that there could have been closer cooperation between the camp and the base hospital; that there had been no provision for an automatic interchange of special personnel; that special instruments and supplies were late in getting to hospitals and overseas, and that hospitals at the port of embarkation should be thoroughly equipped and staffed.

DR. GEORGE B. WOOD said that from their experiences in the otolaryngological department at Camp Meade it would seem that the hemolytic streptococcus found in healthy carriers was not particularly dangerous, but that when there existed an acute infection due to this organism a spread of the infection was very liable to take place unless great care were exercised to prevent contact. He believed the theory of the danger of drop-

let infection to be not quite so great as had been suggested by some. Major Teague in telling him of his work in Manchuria with the pneumonic plague had said he believed one foot would represent the danger zone of coughing, and that for the infection of culture media and guinea pigs a distance within six inches of the patient's face was necessary. Dichloramine-T had been tried in acute coryza with little success. Dakin's solution was found very valuable in clearing up mastoid infections. The use of dichloramine in carriers gave good results with meningococci, but had little effect with the Klebs-Loeffler bacillus.

Lieut.-Colonel V. P. Blair announced that the basis of their treatment of injuries had been the theory that if the patients could be received early there should be no reason why in the majority of instances early healing should not occur. In no part of the body did the tissues, either bones or soft parts, heal more kindly than in the face, and no place was more resistant to infection. In almost every hospital in France in which he saw good dental work being done there was a university man back of that work. In order to give early treatment to face and jaw injuries it was necessary to have surgeons and dentists who would work together. After the St. Mihiel drive there had been in almost every advanced hospital a good dental man. In Colonel Blair's opinion, the face injuries of this war will probably not be over 1 per cent of all injuries. If the war had continued he thought it would have been possible, with the cooperation of the dental men, to get this type of surgery everywhere on the same basis as that of any other surgery.

Dr. S. MacCuen Smith observed that one of the outstanding advances of this recent war had been the recognition of otolaryngology as a specialty in the United States Army. The statement that drooping of the superior-posterior wall as a well-recognized symptom of mastoid disease had fallen somewhat into disrepute he felt should be challenged. Failure to find this evidence of mastoid disease, in his opinion, was probably due to overlooking the fact that the symptom was present only when the higher cells and the mastoid antrum were involved. This did not in any way alter the fact that if the disease were confined largely to the tip, the above-mentioned sign would not be present, but the case just as urgently required operation.

A Discussion of Some Social and Economic Problems Resulting from Acquired Deafness.—Dr. Wendell C. Phillips of New York City said that otologists should be as much interested in the social and economic problems pertaining to deafness as in the treatment of aural affections. There was too great proneness to look upon deafness as a rare condition when such was not the case. The Twelfth United States Census returns showed that 89,287 of inhabitants are totally deaf, and to this number must be added the far greater array of those partially deaf. It was estimated that in the City of New York alone there were at least 100,000 people more or less incapacitated as a result of hardness of hearing, and of these probably 80 per cent. were of the working class. About eight years ago a small company of hard of hearing persons in New York attempted to form an organization which might meet the necessities of the partially deaf. Later some of the otologists and other hearing people became interested. The main objects of the organization were "to assist the hard-of-hearing in the matter of procuring and obtaining employment; to provide full and part scholarships in lip reading; to alleviate the social isolation of the hard-of-hearing, and to assist them in every way." The labors of the society were conducted under education, employment, welfare, and industry. All applicants for membership, he said, presented individual problems which were carefully worked out by expert workers. An advisory board of otologists freely devoted time and advice. Branch leagues had been established in Chicago, San Francisco, Los Angeles, Pittsburgh, Newark, and Philadelphia, and plans were now being formed for a national organization. In addition to the present objects of the organization there would be considered the prevention of deafness in children. With every constituent organization there should be an advisory board of otologists.

Mental and Spiritual Readjustments of Acquired Deafness.—Miss Annetta W. Peck, corresponding secretary the New York League for the Hard of Hearing, said that readjustment was the preparation for complete reconstruction. It meant not only what was done for the deaf but what no one but the persons could do for themselves. In the five years since the New York League for the Hard of Hearing has had its own office Miss Peck had talked with at least a thousand deafened people. The peculiar burden of acquired deafness was that its victims become odd, if not eccentric. When they had relieved a man's material needs it was their part to help him fight their common enemies—depression, timidity, reluctance to take the initiative, and other antisocial characteristics. That deafened people need not be useless was proved by the records of their employment department. They had convinced about 300 business houses that their applicants were employable. They regard a hard of hearing person as an asset in a business office because he concentrates better than others, saying he is better at routine work because he is accustomed to monotony and isolation, and that he does more work in less time because not engaged in the talking going on about him. In the social work of the League there were seen among those who refuse to readjust themselves many who became more or less mentally unbalanced. After fifteen or twenty years of this isolation (and it was by no means rare) two out of three were not normal. Clubs and recreations and, above all, the friendliness of the workers, often bring such wanderers back. A Sunday afternoon club was designed to meet the religious needs of the hard of hearing. The task in social work for the hard of hearing was, first, to readjust ourselves industrially, if need be, but always spiritually, and having done this, to see that everyone who needs this help has it.

Practical Aspects of Readjustment of Acquired Deafness.—Miss Estelle E. Samuelson, Superintendent of Employment Department of the New York League for the Hard of Hearing, said that social service for the deafened must begin with the otologist. When the League was incorporated in 1912 seventeen persons had signed the charter. To-day their membership was nearly six hundred, less than 10 per cent. being hearing persons. The industrial department transacted a business of about $1,400 a year. In the welfare clubs the members play games, dance, and make merry together. They converse freely by lip-reading or pencil, or with the aid of a hearing device. The educational department undertakes the promotion of lip-reading. In the employment and vocational readjustment department there were placed in 1912 20 per cent. of the applicants; in 1918-1919, 85 per cent were placed; 220 out of 261 who applied. About 300 firms had cooperated in giving employment to the hard of hearing. A one-armed, totally deaf man within a short time had been placed by one of the workers at a salary of $4 a day, which later was increased to $6 per day. With little readjustment applicants were placed in practically all lines of work. From statistics it had been noted that many were pursuing work tending to increase their peculiar type of deafness. The author earnestly asked for the sympathetic cooperation of the medical profession.

Dr Francis R. Packard said that those who had to do with deaf people ought to experience some chagrin that they had not sooner seized and developed the idea presented by the representative of the New York League for the Hard of Hearing. It was a regretable fact that there was no institution to care for those handicapped by acquired deafness. The value of the early acquisition of lip-reading was to be emphasized. He was glad the fact had been mentioned that the hearing devices were more of a strain and of less advantage than an early acquaintance with the motion of the lips in making words and the ability to use the eyes to replace the organs of hearing. He urged the cooperation of doctors and laymen in the extension of the movement to all the states of the Union.

Dr. S. MacCuen Smith said that that which had impressed him most markedly in the presentations was the cheerfulness which Miss Peck and Miss Samuelson personally manifested and brought to their work. He inquired whether they advised the use of an aid to hearing early in the process of loss of hearing. It had seemed to him that such early use established premature dependence upon the hearing device. He believed

that all Philadelphia aurists would be glad to cooperate in furthering the work of the League for the Hard of Hearing.

Miss ESTELLE SAMUELSON said that from her own experience she could say that an aid to hearing was not advisable in the first stage of deafness and this she had found to be the experience of many. With the instrument she could hear all sounds, except the voice.

Dr. WENDELL C. PHILLIPS said he believed that the gradually growing deaf patient might well learn lip-reading for the reason that it lessened strain. In his opinion the aid to hearing device should not be used until it was a necessity.

Dr. B. ALEXANDER RANDALL referred to the claim that one adult in three is deaf in one or both ears. From this largely confirmed fact it could be realized to what a large clientele a society such as mentioned was rendering service. In the use of the electric appliance the low tones, he said, were not heard by those whose deafness was due to impairment of the conducting apparatus. The fatigue resulting from the effort to hear prevented the deaf person hearing. It was well known that the inventor of the electro-phone used a big tin dipper. Edison knew that he had to take in a large volume of sound.

Dr. PHILLIPS emphasized the point made by Miss Peck that quite a proportion of the cases of advanced deafness were instances of borderline insanity. The hearing of imaginary noises presented the first symptoms of these cases and rather fine judgment was required in diagnosis. He bespoke for the League for the Hard of Hearing the assistance of the otologists of Philadelphia.

Miss PECK said there were in their office, besides herself, four young women, all slightly deaf; one was not a lip-reader. The other three were put right back in the hearing class by their lip-reading. Looking at them, one would not know they were deaf. She did not advocate the use of an instrument in the case of slight deafness. Lip-reading should be studied in preference. In her own case, since she was busy every day from nine to five, the instrument gave the needed rest for her eyes.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

VIRGINIA STATE BOARD OF MEDICAL EXAMINERS.

Richmond, June 18-21, 1918.

ANATOMY AND HISTOLOGY.

1. Name the bones of the head.
2. Name the twelve pairs of cranial nerves and give the point of exit of each from the skull.
3. Give origin and insertion of pectoralis major, pectoralis minor, and serratus magnus.
4. Give origin, course, and branches of external carotid artery.
5. Bound Scarpa's triangle, mention vessels in it, and give their anatomical relationship.
6. In appendectomy name structures divided from without inwards.
7. Bound anterior triangles of neck, give origin and insertion of muscles forming them.
8. Locate, describe, and give relationship of gall-bladder.
9. Describe the wall of the bladder, give different structures in cross section and kind of epithelium.
10. Name the different kinds of epithelia.

PHYSIOLOGY AND CHEMISTRY.

1. Is lymph a product of the lymphatic glands? (*b*) How is lymph formed?
2. Locate lesion that will cause incoordination of voluntary movement and loss of knee jerk.
3. Trace the course of blood in the adult. (*b*) What changes occur at birth?
4. Name the three portions of the stomach and describe the functions fulfilled by each.
5. What effect on digestion has the existence of a biliary fistula?
6. What is the effect of an abundant diet containing an insufficient amount of protein?
7. What is the relation of the thyroid gland to myxedema, cretinism, and exophthalmic goiter?
8. What effect has the seasons on the specific gravity of urine?
9. What is the difference in action of the "ous" and "ic" compounds of Hg.? Give name of one of each.
10. By what tests can starch be recognized?

MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

1. Name five most efficient anthelmintics, giving doses of each and the parasite upon which the drug is most effective.
2. What are the five most important preparations of mercury, giving dose and use of each.
3. Write a compound prescription having cholagogue action and also stimulating different parts of intestinal canal.
4. What secretions of internal organs furnish extracts of therapeutic value, and give physiological action of each.
5. Give physiological action of digitalis. State in what lesions and conditions it should be used with choice of preparations.
6. In what four ways do diuretics act, and give an example in each class.
7. Name of the official bromides, average adult doses, and chief therapeutic uses.
8. Describe the symptoms caused by a toxic dose of opium. State with what diseases they may be confounded and outline the indicated treatment.
9. Name two neurotic poisons and two corrosive poisons. State upon what organs the specific effects of each are most shown.
10. Give general treatment for poisoning by the stomach and the chemical antidotes for opium, carbolic acid, bichloride of mercury, nitrate of silver, and iodine.

PATHOLOGY.

1. What is the pathology of plastic inflammation?
2. Describe how mitral stenosis and aortic regurgitation respectively affect the cavities and musculature of the heart.
3. What are the degenerative changes of arteries?
4. Differentiate between osteomyelitis and inflammatory rheumatism.
5. What is necrosis? What prevents hemorrhage in gangrenous lesions?

BACTERIOLOGY.

1. What are the three basic forms of bacteria? Describe each form.
2. Define immunity. Explain (*a*) how acquired, (*b*) how destroyed.
3. By examining the fluid of lumbar puncture, how may we distinguish between tuberculous and other forms of meningitis?
4. In what diseases have specific microorganisms been recovered from the blood?
5. How would you diagnose malaria from typhoid fever by the microscope?

ANSWERS.

ANATOMY AND HISTOLOGY.

1. The *bones of the head* are: Occipital, two parietal, frontal, two temporal, sphenoid, ethmoid, two nasal, two superior maxillary, two lacrymal, two malar, two palate, two inferior turbinated, vomer, and inferior maxillary.

2. *Cranial nerves, with foramina of exit from skull:* First, or olfactory, through foramina in cribriform plate of ethmoid. Second, or optic, through optic foramen. Third, or motor oculi, through sphenoidal fissure. Fourth, or trochlear, through sphenoidal fissure. Fifth, or trigeminus, through sphenoidal fissure, foramen rotundum, and foramen ovale. Sixth, or abducens. through sphenoidal fissure. Seventh, or facial, through stylomastoid foramen. Eighth, or auditory, through internal auditory meatus. Ninth, or glossopharyngeal; tenth, or pneumogastric, and eleventh, or spinal accessory, through jugular foramen. Twelfth, or hypoglossal, through anterior condyloid foramen.

3. PECTORALIS MAJOR. *Origin:* Inner half of anterior surface of clavicle, half of anterior surface of

sternum, anterior surfaces of upper six costal cartilages, and upper part of aponeurosis of external oblique. *Insertion:* Outer bicipital ridge of humerus.

PECTORALIS MINOR.—*Origin:* Upper margin and outer surface of third, fourth, and fifth ribs near their cartilages, and from the aponeurosis covering the intercostal muscles. *Insertion:* Coracoid process of scapula.

SERRATUS MAGNUS.—*Origin:* Outer surface and upper border of upper eight ribs and from aponeurosis of the corresponding intercostal muscles. *Insertion:* The ventral aspect of the vertebral border of the scapula.

4. The *external carotid artery* arises at the point of bifurcation of the common carotid artery, opposite the upper border of the thyroid cartilage, passes upward and ends in the substance of the parotid gland behind the neck of the lower jaw, where it divides into the superficial temporal and internal maxillary arteries.

The *branches of the external carotid artery* are: Superior thyroid, lingual, facial, occipital, posterior auricular, ascending pharyngeal, superficial temporal, and internal maxillary.

5. Scarpa's triangle is a triangular area or depression situated just below the fold of the groin. It is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genitocrural nerve. At the apex, the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

6. In *appendicectomy*, the following structures are divided, from without inwards: Skin, fascia, external oblique, fascia, sheath and fibers of internal oblique, fascia, transversalis, fascia, areolar tissue, peritoneum, appendix.

7. The ANTERIOR TRIANGLE OF THE NECK is *bounded:* In *front* by a line from the chin to the sternum; *behind* by the anterior margin of the sternomastoid; *base* is upward, and is formed by the lower border of the body of the lower jaw and a line from the angle of the jaw to the mastoid process. It is *divided* into three smaller triangles (inferior carotid, superior carotid, and submaxillary) by the digastric muscle and the anterior belly of the omohyoid. The *inferior carotid triangle* is bounded, in *front* by the median line of the neck, *behind* by the anterior margin of the sternomastoid, and *above* by the anterior belly of the omohyoid. The *superior carotid triangle* is bounded, *behind* by the sternomastoid, *below* by the anterior belly of the omohyoid, and *above* by the posterior belly of the digastric. The *submaxillary triangle* is bounded, *above* by the lower border of the body of the mandible and a line drawn from its angle to the mastoid process, *below* by the posterior belly of the digastric and the stylohyoid, and in *front* by the anterior belly of the digastric.

STERNOMASTOID. *Origin:* Upper and outer part of the anterior surface of the manubrium sterni, and upper surface of the clavicle at its sternal end. *Insertion:* Outer surface of mastoid process of the temporal bone, and outer part of the superior curved line of the occipital bone.

DIGASTRIC.—The posterior belly arises from the digastric groove on the internal surface of the mastoid process of the temporal bone; the anterior belly from a depression on the inner surface of the lower border of the inferior maxilla, near the symphysis. These two bellies are connected by a central tendon which perforates the stylohyoid, and is bound down to the greater cornu of the hyoid bone by a process of fascia.

OMOHYOID. *Origin:* By means of the *posterior belly*, from upper border of scapula and suprascapula ligament. *Insertion:* By means of *anterior belly*, into the outer third of lower border of body of hyoid bone.

STYLOHYOID.—*Origin:* Posterior and outer side of styloid process of temporal bone. *Insertion:* Anterior surface of hyoid bone at junction of great cornu with the body.

8. The *gall bladder* is a conical bag placed in a fossa on the under surface of the right lobe of the liver. Its upper surface is attached to the liver, and its fundus and posterior surfaces are invested by peritoneum reflected from the adjacent surface of the liver. The body is in relation in front with the liver, and behind with the first part of the duodenum, the pylorus, and the hepatic flexure of colon. The fundus is in contact with the parietes opposite the ninth right costal cartilage. It is about four inches long and holds about one ounce. Its duct passes from the neck of the gall bladder downward, backward, and to the left to join the hepatic duct.

9. *Wall of the bladder:* "There is a mucous, submucous, muscular, and serous coat to the bladder. The *mucous membrane* resembles that of the ureters, with which it is continuous. It is covered with a transitional epithelium whose cells vary according to the distention of the bladder. As a rule, epithelial cells have but very little elasticity and mucous membranes therefore are frequently much folded. The bladder cells are capable of considerable distention, when they become very flat. When the organ contracts they accommodate themselves to this condition and become cubical. The cells of the surface layer are squamous and have concave depressions into which the rounded ends of the second layer or pear-shaped cells are adjusted. Two or more layers of irregular interstitial cells intervene between the apices of the pear-shaped cells. The interstitial cells divide regularly by karyokinesis and are then crowded to the surface to replace the superficial cells that normally exfoliate. A *vascular submucosa* intervenes between the mucosa and the muscularis. This is a thin layer of areolar tissue, but sufficient to give the mucosa apparent elasticity and enable it to move upon the muscularis. The *muscular coat* consists of smooth muscle fibers which may be divided into bundles of outer longitudinal fibers, a middle strong circular layer, and an imperfect inner longitudinal or diagonal stratum. At the urethral opening the middle layer is thickened to form a sphincter muscle, according to some authors. The bladder musculature forms a basket-work fabric, and when much distended intervals may arise in its walls which become points of weakness through which the mucosa may protrude, when the organ is said to be sacculated."—(Hill's *Histology.*)

10. KINDS OF EPITHELIUM. (1) *Pavement* or *Squamous:* A single layer of flat, nucleated cells, cemented together at their edges. (2) *Stratified:* In layers of cells that are unlike in form. (3) *Columnar:* Tall, cylindrical cells arranged in a single layer. (4) *Cuboidal:* Similar to columnar, but the cells are shorter. (5) *ciliated:* Columnar cells with hair-like processes (cilia) on their free surface. (6) *Goblet:* Cylindrical cells distended with mucin. (7) *Transitional:* When the cells are neither arranged in a single layer, like squamous, nor yet in many superimposed layers, like stratified, but in two or three layers.

PHYSIOLOGY AND CHEMISTRY.

1. Lymph is not a product of the lymphatic glands. *Formation of lymph:* There are three main theories: (1) Ludwig's theory, or the filtration theory, coupled with osmotic changes between the lymph and blood; (2) Heidenhain's theory of lymphagogues; and (3) Starling's theory of the permeability of the capillary walls. The subject is summed up by F. A. Bainbridge as follows: "Lymph formation is not a secretory process, but is brought about by purely physical processes, namely, filtration and osmosis; and the factors concerned in its production are (1) the capillary pressure, (2) the degree of permeability of the capillary walls, and (3) the metabolic activity of the tissues. There is no reason to suppose that in health the permeability of the capillaries alters, and therefore the formation of lymph is increased chiefly by variations in the first and third of these factors."

2. These conditions are found (with others) in locomotor ataxia, in which disease the lesions are situated in the posterior columns of the spinal cord and the posterior nerve roots.

3. The *circulation of the blood* is the course or cir-

cuit of the blood from the heart, through the body and back to the heart. Beginning at the left ventricle of the heart, the blood flows through the left semilunar valve into the aorta, from which branches are distributed to every part of the body, through the capillaries to the veins, from the veins to the venæ cavæ, thence to the right auricle of the heart. From the right auricle, through the tricuspid valve to the right ventricle, thence through the right semilunar valve to the pulmonary artery to the lungs, from the capillaries in the lungs to the pulmonary veins, then to the left auricle, and through the mitral valve to the left ventricle, to begin the circuit again.

Differences between the fetal circulation and that of the adult: In the *fetus* there is direct communication from the right auricle to the left auricle by the foramen ovale; the Eustachian valves are larger, the heart is relatively larger; there is communication between the pulmonary artery and the descending aorta by means of the ductus arteriosus; there is communication between the internal iliac arteries and the placenta by means of the umbilical or hypogastric arteries; and the presence of the ductus venosus which unites the umbilical vein and the inferior vena cava.

Changes that occur in the fetal circulation at birth: The hypogastric arteries dwindle and close, the foramen ovale becomes obliterated, the ductus arteriosus and ductus venosus become obliterated, the umbilical vein becomes impervious, and the Eustachian valve atrophies.

4. The *three portions of the stomach* are: (1) The *fundus*, which serves as a reservoir in which the food is gradually mixed with the gastric juice. (2) The *intermediate* or *prepyloric part*, in which the hydrochloric acid of the gastric juice is mainly secreted. The churning movements occur in this part as well as (slightly) in the fundus. (3) The *pyloric part*, which pushes the food through the pylorus into the duodenum; this part also takes the chief part in the trituration and maceration of the food. The peristaltic waves are most forcible here.

5. When a *biliary fistula* is present a large part of the fat of the food is not absorbed, and is found in the feces; digestion of proteins and carbohydrates is delayed.

6. An *insufficient supply of protein in the diet* leads to lowered power of resistance, imperfect tissue repair, and tendency to pallor and puffiness of the body.

7. *Myxœdema* occurs in an adult when the thyroid gland atrophies or when its functions become seriously impaired; also, sometimes, after removal of the thyroid.

Cretinism occurs in children when the thyroid gland is absent or atrophies at an early age.

Exophthalmic goiter occurs when the thyroid gland is greatly enlarged, or its functional activity much increased.

8. The *specific gravity of the urine* varies with the amount of urine voided in twenty-four hours, the gravity increasing as the quantity is diminished. In cold weather more urine is voided, so the gravity should be less in winter and greater in summer.

9. The *mercurie* salts are more irritant and poisonous than the *mercurous* salts.

Mercurous chloride, or calomel; mercuric chloride, or corrosive sublimate.

10. *Tests for starch:* (1) A dilute solution of iodine gives a violet-blue color with starch. (2) The microscope shows the characteristic starch granules with their concentric markings.

MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

1. FIVE ANTHELMINTICS.—(1) *Thymol*, dose gr. x-xij; against hookworm. (2) *Santonin*, dose gr. j; against round worm and thread worm. (3) *Pelletierine*, dose gr. xxv; against tapeworm. (4) *Aspidium*, dose half a dram of the oleoresin; against tapeworm. (5) *Pepo*, dose 15 grains of the resin; against tapeworm.

2. FIVE PREPARATIONS OF MERCURY.—(1) *Hydrargyri chloridum mite* (calomel), dose gr. ss to x; used in syphilis, as a laxative or purgative, in congested or cirrhotic liver, in diarrhea, and as a diuretic. (2) *Hydrargyri chloridum corrosivum* (corrosive sublimate), dose gr. 1/60 to 1/30; used as an antiseptic, disinfectant, antiparasiticide, in syphilis, interstitial nephritis. (3) *Liquor arseni et hydrargyri iodidi* (Donovan's solution), dose ℥ij; used as an alterative. (4) *Hydrargyrum cum creta*, dose gr. ss to x; used in syphilis, diarrhea, biliousness. (5) *Massa hydrargyri*, dose gr. ss to x; used in biliousness, fevers, diarrhea.

3. *Cholagogue:*

℞ Resinæ podophylli.....gr. vj
Extracti belladonnæ foliorum.....gr. iij
Pulveris capsici
Pulveris sacchari lactis.....āā gr. xxiv
Pulveris acaciæ.....gr. vj
Glycerini
Syrupi.....āā q. s.

Fiat massa in pilulas No. xxiv dividenda.

Signa: Take one or two, as required.

4. *Action of Thyroid extract:* "It is a powerful vasomotor dilator, causing flushing of the cutaneous surface; large doses are apt to produce loss of appetite and diarrhea; it stimulates the cerebrum and, given to excess, produces headache, restlessness, insomnia, palpitations, hot flushes, sweating, tremors, and even convulsions; it is excreted by the kidneys, and the quantity of urine is uniformly increased by it; it induces a greatly increased oxidation in the system."—(Wilcox's *Material Medica.*)

Action of Suprarenal extract: "It is a strong cardiac stimulant, slowing the pulse rate and affecting the heart muscle in the same way as digitalis; it is a powerful vasoconstrictor and raises blood pressure more than any other known substance; it increases the tone of all muscular tissue; it causes diminution of peristalsis and a depression of the respiratory center, which may result in respiratory failure and death."—(Wilcox's *Materia Medica.*)

Action of Thymus extract: It is supposed to be concerned in the formation of bone salts, to be a reconstructive, and to have a hemostatic action.

Action of Pituitary extract: It stimulates the heart and contracts the blood vessels, but not so powerfully as the suprarenal extract does.

5. DIGITALIS.—*Physiological action:* It is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure, it also acts as a diuretic. *Therapeutic use:* Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is *contraindicated* in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc. *Dangers: Overdose or constant use* will cause irregularity of the heart, headache, vomiting; and hobbling dicrotic pulse, particularly when the patient changes from the recumbent to a sitting posture. In *cardiac conditions*, the tincture should be used; when it is employed as a diuretic, the infusion is indicated.

6. *Diuretics act:* (1) By increasing the general arterial pressure (as digitalis); (2) by dilating the renal vessels (as caffeine); (3) by drawing water into the blood (as potassium citrate); (4) by stimulating the renal epithelium (as calomel).

7. The *official bromides* are: Potassium bromide dose 15 grains; sodium bromide, dose 15 grains; ammonium bromide, dose 15 grains; lithium bromide, dose 15 grains; calcium bromide, dose 15 grains; strontium bromide, dose 15 grains.

Physiological action: "The bromides in concentrated solution are gastrointestinal irritants. They are directly depressant to the cerebrospinal axis, producing lassitude, drowsiness, and sleep (which, however, is never very deep), with marked diminution of reflex irritability and of the respiratory and sexual functions. They are diuretic, especially the lithium salt, and are excreted mainly in the urine, but to some extent also in the perspiration and milk, and probably by the bronchial and intestinal mucous membrane. Potassium bromide weakens the heart's action and is also more depressing to the central nervous system than the other. Lithium bromide is the richest in bromine and is thought to have the most pronounced hypnotic effect

The strontium and calcium salts are said to produce less digestive disturbance than those of the alkalies, but they appear to be absorbed more slowly. In bromism, or chronic poisoning, there are acne or other skin eruptions, a catarrhal condition of the mucous membranes, derangement of digestion, diminished sensibility, especially of the faucial mucous membrane, uncertain gait, dulled intellect, impairment of memory, and an apathetic expression of countenance.

"*Uses:* The bromides constitute our most valuable remedy for epilepsy, but as they must be continued for a long period, every effort should be made to minimize their injurious effects upon the system. They are much used also, either alone or in combination with other drugs, in the treatment of insomnia, nervousness, hysteria, neuralgia, migraine, delirium tremens, seasickness, seminal emissions, nymphomania, and various forms of convulsions. Except in cases of epilepsy they should not, as a rule, be given continuously very long, on account of the danger of the patient's contracting the bromide habit."—(Wilcox's *Materia Medica.*)

8. The *symptoms of poisoning by opium* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somenolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."

Treatment: "Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach, and maintain the respiration. In the first or second stage the 'ambulatory treatment' should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop, the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee or caffeine, by the mouth or rectum, are of benefit. The same cannot be said of atropine. The urine should be drawn by the catheter."—(Witthaus' *Essentials of Chemistry.*)

The coma of opium poisoning may be confounded with the coma of cerebral hemorrhage, alcoholic coma, uremic coma, and diabetic coma.

9. *Two neurotic poisons:* Opium, and hydrocyanic acid.

Two corrosive poisons: Mercury, and potassium hydroxide.

The effects of the *neurotic poisons* are most seen in the brain and spinal cord. The effects of the *corrosive poisons* are most seen in the tissues with which they come in contact—generally the mouth, esophagus, and stomach.

10. *Treatment for poisoning by opium:* See QUESTION 8. The chemical antidote is potassium permanganate.

Treatment for poisoning by carbolic acid: Sodium sulphate or magnesium sulphate, warm mucilaginous drinks, cardiac and respiratory stimulants by hypodermic, warmth to the body, emetics, are all indicated. Alcohol may also be administered. The chemical antidote is alcohol or a soluble sulphate.

Treatment for poisoning by bichloride of mercury: The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

Treatment for poisoning by nitrate of silver: Milk, mucilaginous drinks, and an emetic; the chemical antidote is sodium chloride.

Treatment for poisoning by iodine: Emetics, followed by washing out the stomach with a solution of starch. Starch is the chemical antidote.

PATHOLOGY.

1. *Plastic inflammation* "is characterized by the formation of a firm, false membrane, due to the coagulation of the plasma exuded from the vessels, the resulting fibrin being deposited on the surface. When involving a serous surface, such as the pleura, peritoneum, or synovial membrane, it gives rise to a layer of plastic lymph, which may organize into adhesions; it is also seen in the alveoli of the lungs in lobar pneumonia. On mucous membranes, such as the conjunctiva or that of the pharynx, it occasionally forms white, flaky masses, which can be readily detached, leaving an injected surface below, with merely one or more oozing points, and no loss of substance."—(Rose and Carless' *Surgery.*)

2. In *mitral stenosis* "there is an increase in the intra-auricular pressure toward the end of auricular diastole, due to the blood from the lungs flowing into an insufficiently emptied auricle; the consequent dilatation and stretching excite the auricle to very vigorous contractions, which become augmented in consequence of the obstruction to the discharge of blood. The result is an extraordinary enlargement (hypertrophy and dilatation) of the left auricle, which may attain dimensions three or four times the normal. Increased intrapulmonary pressure is followed by hypertrophy and dilatation of the right ventricle."

In *aortic regurgitation* "the left ventricle during diastole receives blood from two sources—the normal volume from the left auricle and a variable amount, the regurgitating stream, from the aorta. The intraventricular diastolic pressure becomes increased. The tension and stretching to which the ventricular musculature is thus subjected stimulate it to vigorous contractions, and ultimately induce more or less hypertrophy. The enlargement of the cavity of the ventricle (dilatation) and the concomitant hypertrophy may, and usually do, counterbalance each other. Ultimately the heart may reach enormous proportions, the largest seen."—(From Kelly's *Practice of Medicine.*)

3. The *degenerative changes of arteries* are: Fatty degeneration, amyloid degeneration, hyaline degeneration, and calcification.

4. In *inflammatory rheumatism* the pains and symptoms in general are in connection with the joints, whereas in osteomyelitis the shaft of the bone is more apt to be affected; there is no suppuration in the rheumatism, in osteomyelitis there is; in rheumatism the pain and fever can often be lessened by the administration of salicylates; this is not so marked in osteomyelitis.

5. *Necrosis* is death of a limited portion of tissue in the living body. It is generally due to want of nutrition due to the cutting off of the blood supply to the part (this may be caused by thrombosis, embolism, pressure, or ligature), and this accounts for the lack of hemorrhage in gangrenous lesions.

BACTERIOLOGY.

1. The *three basic forms of bacteria* are: Cocci, bacilli, and spirilla. *Cocci* are spherical or oval, and may appear singly, in pairs, in chains, or in groups. *Bacilli* are rod shaped, with the longer sides parallel and the short ends either straight, rounded or concave. *Spirilla* are spiral, with one or more curves.

2. *Immunity* is the power of resistance of the cells and tissues of the body to the action of pathogenic microorganisms. Immunity may be either natural or acquired.

Natural immunity is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The chief conditions which give immunity are: (1) A previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Immunity may be destroyed, by: Lapse of time, lessened resistance or vitality of the body, cold, wet, fatigue, improper or insufficient food, excesses of all kinds, certain drugs, and improper environment.

3. The cerebrospinal fluid should be received in a

sterile container, and then centrifuged. The *laboratory methods of diagnosis of tuberculous meningitis* are finding the tubercle bacilli in the cerebrospinal fluid, cultivating them from the same, and injecting rabbits or guinea pigs with the fluid or sediment, and causing tuberculosis in these animals.

The *cerebrospinal fluid* may be clear or turbid when drawn, but a slight deposit forms on its being allowed to stand. There is a decided increase in the lymphocytes and polynuclears in the fluid, and the tubercle bacilli may be found in the fluid or the sediment. The fluid is increased in quantity; its protein content is also increased.

4. *Specific microorganisms have been recovered from the blood,* in the following diseases: Typhoid, septicemia, pyemia, osteomyelitis, pneumonia, influenza, diphtheria, gonorrhea, tuberculosis, anthrax, bubonic plague, syphilis, leprosy, malaria, trypanosomiasis.

5. *In examining for malaria:* "Prepare some perfectly clean and very thin cover slips, and remove all traces of grease. Cleanse the skin of the finger-tip or ear with soap and water, and then with alcohol and ether. Make a *small prick* in the skin. Wipe away the first drop of blood, leaving a perfectly dry surface, so that subsequent drops will not run. Squeeze out a tiny drop about the size of a large pin's head. Touch the apex of this drop with the center of a cover glass, and immediately drop it, face downward, on a perfectly clean slide. Make several such preparations, and reject all those in which rouleaux are present. It is absolutely essential that the red corpuscles should lie flat. Examine with a 1/12 immersion lens and rather feeble illumination. Look in the red corpuscles for the presence of small black specks, often rod-like and showing slow movements of translation. These are surrounded by clear areas. One may also see in the center of some of the red cells clear ameboid areas which show no pigment. Rosette forms may also be visible. These forms of the parasite are always present in cases of malaria which have not had quinine. Other varieties are only met with in some chronic cases. Of these there are two chief forms: (1) The crescentic, (2) the flagellated. These are easily recognized. The crescentic bodies are highly refractile, rather longer than a red blood corpuscle, and about 2μ in diameter. Particles of pigment may be recognized in the parasite and also in some of the ordinary leucocytes."—(Hutchinson and Rainy.)

Further, in *malaria* the Widal test is negative.

In *typhoid* the Widal test will probably be positive, and there will be no malarial parasites in the blood.

The Widal reaction: "Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses of clumps, and cease their rapid movement inside of twenty minutes."—(From Thayer's *Pathology.*)

(*To be continued.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	S. W. Welch, Montgomery	Montgomery	July 8
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix	Phoenix	July 1
Arkansas	T. J. Stout, Brinkley	Little Rock	May 13
California	C. B. Pinkham, Sacramento	San Francisco	June 23
Colorado	David A. Strickler, Empire Building, Denver	Denver	July 1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 8
Delaware		Wilmington	
Dist. of Col'bia	E. P. Copeland, Washington	Washington	July 8
Florida*	W. M. Rowlett, Tampa	Jacksonville	June 16
Georgia	C. T. Nolan, Marietta	Atlanta	June 5
Idaho*	Ray H. Fisher, Rigby	Pocatello	
Illinois	F. C. Dodds, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	
Iowa	G. H. Sumner, Des Moines	Iowa City	
Kansas	H. A. Dykes, Lebanon	Topeka

National Board	J. S. Rodman, 1310 Medical Arts Building, Philadelphia	Philadelphia	June 2

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Cysticercus Bovis in the Human Breast.—Fontan reports the following case. A woman aged forty-five years consulted for a small swelling in the left breast not larger than a cherry pit. It lay outside the nipple area, was hard and non-adherent. Five axillary lymph nodes were inflamed. Cancer, tuberculosis, and syphilis could be eliminated and the residual diagnosis was adenoma. The woman demanded to be freed from this infirmity, irrespective of the hazard. The examination of the stools chanced to reveal segments of a tenia saginata, and a tenifuge led to the complete expulsion of the worm. The cyst was excised and was found to contain the head of the parasite in question, corresponding in every way to the expelled parasite's head. The case was therefore one of so-called "ladrerie," that dread medieval affection, which is fortunately very rare at present."—*La Presse Médicale.*

On the So-called Graser's Diverticle in the Sigmoid Flexure.—Basilier describes a case of diverticle formation in the sigmoid flexure in a man of 49 who came to operation with pronounced symptoms of intestinal occlusion. The laparotomy showed the presence of a diverticle the size of the little finger and 10 cm long, the distal extremity of which was adherent to the abdominal wall and great omentum. It was also fused to the ileum in three different places as a result of abscess formation. The loops of ileum at the sites of adhesion were markedly narrowed. Moreover the sigmoid itself was stenotic at the point of origin of the diverticle. Its wall was thickened, with bulging into the lumen. The piece of sigmoid resected included the diverticle and stenotic area. For the first 10 days after operation the condition of the patient was excellent. The pulse was good, the bowel movements spontaneous and the temperature but slightly elevated; then after an enema the patient suddenly collapsed and on the 14th postoperative day died of diffuse peritonitis. Autopsy revealed a small, gaping opening at the site of origin of the diverticle. The microscopical examination revealed that in this Graser diverticle not all of the intestinal tunics were present. The wall consisted chiefly of dense connective tissue and the mucous layer was here and there necrotic. No muscle elements were present. This anomaly is doubtless responsible for much so-called perisigmoiditis.—*Finska Läkaresällskapets Handlingar.*

THE ETIOLOGY OF PNEUMONIA AND ITS SERUM TREATMENT.

BY FENTON B. TURCK, M.D.,

NEW YORK.

EXPERIMENTAL evidence shows that tissue cell substance of the animal species to which it belongs, and not the ferments, determines the specific action on the organism. The ferments of microorganisms (trypsin, pepsin, and erepsin) must first digest the tissue of the "infected" animal before disease occurs, and so-called "specific infection" is but the reaction on the tissues or organ involved. As we have shown,[1] the injection or the absorption of the poison of self-digested tissue of the animal or of the tissue belonging to the same species causes definite lung lesions. The most classical form of lung disease occurs when products of autolyzed lung tissue of the animal or of an animal of the same species reach the lung by the bronchial tubes or the (capillary) circulation in the lung.

The following experiments with autolyzed lung tissue, made absolutely free from microorganisms, show that it is the products of digested lung tissue and not the microorganisms that produce lung disease.

Method.—Fresh normal cat's lung tissue was autolyzed in a sterile chamber of chloroform vapor for 48 hours. No bacteria were found, microscopically or by culture, in the autolyzed tissue products, which gave a strong biuret reaction. A special tube attached to a respiratory indicator was inserted into the cat's trachea and 0.5-1 gram emulsion of this sterile autolyzed lung tissue was insufflated into the trachea. By the animal's increased inspiration a small part of this lung tissue product was aspirated into the finer bronchi and caused death of the animal within four minutes. In other animals typical pneumonia occurred of both bronchial and lobar forms. In cases of immediate death the tissue changes in the lungs were focal in type, with disseminated hemorrhagic areas, while the entire lung was hyperemic; in some cases it was soaked with blood.

General Findings and Discussion.—A comparatively small amount of the lung toxin reached the finer bronchioles, but only a very small quantity was needed to cause these acute conditions and death. When the amount of fine lung tissue toxin was much diluted on reaching the lung tissue cells, death was delayed, and pneumonia of both bronchial and lobar types resulted. In those instances in which death was delayed, classical pneumonitides of bronchial type, with numerous focal lesions, becoming hard and resistant, were observed. If the pneumonic process continued for a week or ten days typical lobar pneumonia resulted, with hepatization. The interesting fact observed was that no reaction in the early stages was apparent in the trachea or bronchi, which appeared quite normal.

TABLE—CATS INSUFFLATED WITH AUTOLIZED CAT LUNG TISSUE

Cat. No.	Time of Death After Insufflation.	Time of Examination Made Under Anaesthesia.	Pneumonic Findings on Immediate Post Mortem.		Remarks
			Bronchial Type.	Lobar Type.	
P 1	4 min.			+	Intense congestion of both lungs.
P 2	3 min.		+		Lungs appeared soaked in blood.
P 3	5 min.		+		Liver lobes involved and lungs congested.
P 4	10 hrs.			+	Sneezing. Rales.
P 5	.....	45 hrs.	+		Rales.
P 6	24 hrs.		+		Coughing.
P 7	Shock	25 min.	+		Resection of lungs.
P 8	15 min.		+		
P 9	5 hrs.		+		Profound symptoms from the beginning.
P 10	10 days		.....	+	Pleuritic effusion.
P 11	8 days		.....	+	Coughing and sneezing.
P 12	.....	3 days	+		Coughing. Rales.
P 13	3 min.		+		
P 14	2 hrs.		+		
P 15	36 hrs.		+		
P 16	4 min.			+	Intense engorgement
P 17	5 min.		+		Reaction in both lungs
P 18	Shock	5 min.	+		Reaction in both lungs. with hemorrhages.

The pathological lesions in the lung produced by the absorption of autolyzed tissue products are similar in character to the lesion produced when the homologous tissues are autolyzed in *vitro* and injected intravenously into the animal. A glance at the finer histological elements in the lung alveoli and the relation to the capillary blood supply will make the pathology more clear. Each bronchiole branches into small ducts which widen out into several alveolar ducts and lead into the air sac or alveolar sac. Small depressions in the walls of the air sac are the saccules or alvei. The fine bronchioles, small ducts, and alveolar sacs and saccules are all lined throughout with thin squamous epithelium. Communication between one system of respiratory chambers and its neighbor is said to exist by small channels or pores. The capillary network of the blood supply of the air sacs from the pulmonary artery is the densest capillary plexus in the body.

The endothelial cells of the capillaries and the thin respiratory epithelium forms the thinnest partition between the air space and the blood which permits the instantaneous exchange of gases, and

also the absorption of nutrient matter as well as the excretion of waste. All the alveolar sacs, ducts and finer tissues are supplied by the pulmonary artery. The effete waste from the blood on one side and products within the finer bronchi and air sacs on the other have opportunity of prompt and ready reactions with the blood. The most effective reaction can be produced by autolyzed lung tissue. The injection of autolyzed lung tissue into the blood causes instant engorgement of all of the lung capillaries. If instead of injection in the blood vessels the autolyzed lung tissue is insufflated into the trachea it reaches the respiratory epithelium and the same instantaneous pulmonary congestion takes place, death occurring usually in three or four minutes. It is in this zone that the reaction takes place when autolyzed tissue products reach the lung by the blood stream and the respiratory epithelium appears to determine the reaction. But of great practical interest is the remarkable fact that autolyzed lung tissue insufflated into the bronchi causes no reaction of the respiratory tract until it reaches the respiratory epithelium which is in virtual contact with the endothelium of the capillaries. No pathological changes are seen in the trachea or the bronchioles, but the reaction originates in the distal portion of the bronchial alveolar system connected with the surrounding dense capillary plexus. When death is delayed the reaction extends up to the bronchial mucosa and classical pneumonitis of the bronchial type appears with acute catarrhal symptoms. This extension is secondary to the reaction in the alveolar system just described. The extension of the "catarrh" and congestion of the respiratory mucosa passed *upward* to the pharyngeal and nasal mucosa and into the nasal ducts and conjunctiva.

The method by which the autolyzed lung tissue may be carried into the trachea under more natural conditions is shown by the following experiments.

Cats Paws Covered with Thin Paste of Cat Autolyzed Lung Tissue.—The cat lung tissue was autolyzed under the same sterile conditions as in the previous experiments.

A group of ten cats was selected and examined to exclude any respiratory disturbance, and then placed in a large cage. The front paws of five of these animals were coated with a thin paste of the autolyzed cat lung tissue. The animals were tagged and placed back in the cage with the other five cats that had not had the application of "lung paste." Within two hours several of the cats began to sniffle and sneeze. Within twelve hours all the cats, those that had had their paws coated and the others in the same cage that had not had the application of paste, had symptoms of involvement of the lungs. Eight of these cats died from pneumonia within 48 hours to one week after the application of the lung paste. Some of the animals showed extensive respiratory pathological conditions. They also showed nasal discharge, eyes reddened, conjunctive discharging and extensive rales over both lungs. The temperature at first dropped and later rose, but the temperature records were no guide to the degree of lung involvement.

The post-mortem findings were similar in character to those in which the lung tissue was insufflated into the trachea. In some of these animals the lungs showed acute hemorrhagic pneumonitis. In others there was hepatization of lobar type with dense hardened nodules. In others again both types were shown in the same lung.

The early changes seemed to be confined to the capillary areas of the pulmonary arterial zone. High viscosity and clotting of the blood was found early, with blood stasis and areas of hemolysis.

These experiments have been repeated many times with different animals, but as would be seen by the controls the reactions were chiefly confined to the species.

Controls.—The insufflation into cats of autolyzed dog, beef, sheep, rabbit, and horse lung tissue did not result in pneumonia or death. The spreading on cat paws of autolyzed lung tissue from these animals did not result in respiratory disease or death; single intravenous injections of alien autolized tissue was likewise negative.*

Pneumonia organisms, Types I, II, III, and IV, insufflated into the trachea of cats or any of the other animals, does not produce acute pneumonia, provided, as is well known, that "flooding" the respiratory tract does not occur. The insufflation of large amounts of any ferments or enzymes that occur with bacterial cultures may cause destruction of lung tissue in the animal and excite pneumonitis. The spraying of the pneumonia group directly into the nostrils and throat of the animal did not cause pneumonitis and the animals did not die. One animal sprayed with hemolytic streptococci developed an abscess in the hind leg.

Chloroform insufflated into the trachea, or any chemical substance that caused destruction of lung tissue would ultimately produce in a certain number of animals a condition of pneumonitis. This was the same in effect, as I have shown, as when chloroform is injected into the skeletal muscle tissue of the body.†

The following are the different methods of producing pneumonia with autolyzed lung tissue products. (1) Tracheal insufflation by intubation and aspiration into the bronchi. (2) Intratracheal injection with needle syringe. (3) Intravenous injection. (4) Subcutaneous injection. (5) Spraying with nebulizer among the animals in the cage. (6) Direct spray into the animal's nostrils. (7) Application of "lung paste" to cats' paws.

Controls.—Dog, beef, sheep, horse lung tissue, bacterial cultures, pneumonia, Types I, II, III IV. Streptococcus hemolyticus, and staphylococcus No animals made immune with antiserum here described died from pneumonia when subjected to the same insufflation of lung tissue or paws covered with the lung paste.

Subacute and Chronic Conditions.—The value o this experimental work in lung pathology with autolyzed tissue of the species of the animals used is that the pathological conditions and death are so immediate, so dramatic, so intimately connected

*Jackson[2] found that bronchially-lodged bones and meat, though fine and soft with bacterial putrefaction caused but slight effect.

†Weiss, Kolmer & Steinfield found that normal human lung when injected into animals by various routes was one-fifth (1/5) as toxic as "pneumonia tissue." Weiss concludes that neither undigested pneumococcii protein nor albumin derived from lung tissue possessing sensitizing power are demonstrable in pneumonic exudate.

with the causative factors that there is no escape from forming a definite conclusion. The introduction of the autolyzed products by way of the bronchi and by the circulation gives practically similar prompt reactions and death.

In chronic conditions similar reactions may be traced, although the chronic status is always more involved than the acute condition.

Immunity.—The reason why it has been so difficult to immunize against most of these microrganisms is that effort has made to immunize against the bacteria and their ferments when in reality the determining direct active toxin is the digested tissue products of the host against which immunity must be established to be effective.

Lamb and Brannin[4] in their recent report on pneumonia arrived at the same conclusion of the Public Health and Allied Congress reports, which the writer recently quoted (1919)[1], showing the utter failure of the attempt to immunize specifically against any type of bacteria or their toxins. Wells and Osborne (1913)[3] show that a single protein molecule can act with and produce more than one antibody. According to Lamb and Brannin[4] there was no apparent specific action in any type of serum or bacterial filtrate. The same results were obtained from antimeningococcic, antitetanic, and antidiphtheria sera as from antipneumococcic serum. The final results were the same as others experience in pneumonia treatment as they conclude, "In view of our death rate which we know was about the average," but there was obtained from the free use of these sera and bacterial filtrates, a lessening of the hemorrhagic tendency. They also add, "No improvement resulted unless a reaction occurred." This is most significant confirmation in line with our experimental active immunity. I have frequently noted that these bacterial filtrates and "anti" sera, while nonspecific, do cause (by their enzymes) cell necrosis and autolysis in the injected animal. If these injections are repeated in small doses I obtained antibodies against the animals' own tissue poisons providing there was a reaction.[1] If autolized tissue is the specific toxin to the species it should be able to produce a specific antibody. This I have been able to obtain by repeated injection of autolyzed human tissue into horses. At the end of six months a protective and curative serum was obtained. While native autolized tissue may be specific poison, it is in a sense foreign because it is not only not living but is disintegrated. It therefore creates a reaction in the organism. The writer uses those agents that he can control to more exact doses to cause tissue autolysis, hence chloroform has been used in connection with use of the *specific antisera.*[1] The "antitoxin" or immune sera results in the brilliant specific immunizations against a variety of diseases that are associated with tissue autolysis.

Method of Preparation of the Specific Immune Serum.—For the animal experimental work, goats are used to produce the immune sera, and for clinical work we used horses.

The preparation of the antigen "A" is a nonbacterial autolized tissue under chloroform vapor, and kept sterile with tricresol. This is injected intravenously into the animal at regular intervals for six months. Antigen "B" is used especially in control work which represents the same as antigen "A" but with the addition of bacteria to hasten tissue autolysis.

The tissue selected for the autolysis in antigen "A" is the heart, "B" the lung and "C" the muscle wall of the stomach and duodenum. Goats for experimental work are intravenously injected first twice a week then once a week for six months. The horses for the production of clinical sera are injected intravenously with human autolyzed tissue three times a week and later once a week. This is continued for six months when a high titer of antisera is obtained.

The production of similar sera has been attempted but for somewhat different purposes. Weichardt (1912) claims to have demonstrated by muscular fatigue a toxin called kenotoxin against which an antitoxin may be obtained.

The "cytotoxin" or cytolytic antibodies that have been prepared have proven defective. Pierce describes the method as follows. "A rabbit is injected intraparietal with 'tissue cells' from various organs for only three doses, as subsequent doses increase the danger of losing the animal." The animal is bled one week after receiving the three injections. One of the uses of these "cytotoxins" was with the idea of treatment of cancer by destruction of the cancer cells. Wells concluded that owing to the uncertain state of the subject of "cytotoxin," it may be dismissed, which was similar to the conclusion of Kolmer, as "their use had been disappointing." Wells further remarks: "It may be said, however, that recent developments indicate that various tissues not only contain proteins which exhibit the species characteristic of the entire animal, but also other proteins or antigenic radicals which are more or less independent of these and characteristics to a certain degree for the tissue from which the antigen was obtained. This being the case, we cannot consider the problem of specific cytotoxins a closed chapter; improved methods for separating our antigens may yet enable us to secure antibodies specific for a single tissue or organ."

Zinsser says: "The cytolytic antibodies may be quite distinct from the albuminolytic amboceptors which are developed against unformed antigens."

In my experimental work and in the sera for clinical use it requires six months of carefully graded dosages and prepared human antigen to obtain the specific antisera that we now use.[1]

The success in all animal experiments has been well confirmed by clinical application of the sera to a large number of cases and variety of conditions.[1]

The reports from hospitals and private practice have rapidly accumulated so that a large statistical record confirms the valuable scientific comparative study in animal experiments.

14 EAST FIFTY-THIRD STREET.

SYPHILIS OF THE LUNGS.*

By M. FORD MORRIS, Jr., M.D.,

ATLANTA, GA.

SYPHILIS has been in our midst for lo! these many years—so long, in fact, that "the mind of man runneth not to the contrary." It is possible that lues venerea made its début into human social and sexual circles soon after Madame Eve partook of the forbidden fruit. Anyway, about two centuries before the dawn of Christianity, a Chinese named King described the symptoms of syphilis. In the Bible the references to the "emerods in the secret parts, the unclean man with a "running issue of the flesh," and to the "itch whereof thou canst not be healed" are very suggestive of luetic infection. Syphilis may have been present when the daughters of Moab vexed the Israelites with their wiles; and surely it had a most excellent opportunity to become a skeleton in the closet of every member of the various so-called religious cults of Rome, Assyria, and Asia Minor, whose doctrines taught and encouraged the wildest license, and whose "holy" meetings were nothing more than sexual debauches. In any event, we know that some Spanish sailors contracted this disease in Haiti, in the fifteenth century, and that they soon syphilized Barcelona. At the end of the fifteenth century the syphilitic soldiers of Charless VIII carried this disease to Naples. And then the pox swept over Europe. Commenting upon the lamentable prevalency of syphilis at this time, Astruc made the oft quoted statement that every one, from the Roman pope to the lowest scullion in Christendom, was infected with syphilis. Since that time the pox has traveled to every latitude and longitude, and has left its mark upon some door in almost every community. In the war just ended syphilis played havoc with soldiers of every army.

Although the pale spirochete multiplies within the bodies of an appalling percentage of the earth's human inhabitants, and affects every organ and tissue, excepting possibly the prostate gland, this organism attacks infrequently the lung. In 1898 there were in the London museums but twelve specimens of this condition. In some 2,800 autopsies done at the Johns Hopkins Hospital, reviewed by Osler, there were but twelve cases of syphilis of the lungs, of which number eight were of the congenital type. Among 3,000 autopsies done at the Massachusetts General Hospital, Lord found only one case showing indurative pneumonia, with cavity formation. In a study of 4,880 autopsy protocols Symmers found the lung involved in twelve cases and the presence of syphilitic pleural scars in two more. Even though this condition is comparatively rare, it is probably recognized more frequently now than formerly it was.

Depending upon either the prenatal or postnatal beginning of the syphilitic process, pulmonary lues is usually considered from the hereditary and the acquired aspects.

Inherited Syphilis of the lungs is of two kinds: circumscribed and diffused, the former being known as "gumma" and the latter as "pneumonia." Hereditary pulmonary gummata are rare and differ in no way from the acquired form. The diffuse form is known either as "white pneumonia" or "interstitial pneumonia"—but these two lesions usually are combined. Virchow described a diffuse change in the lungs of stillborn children or those who lived only a few hours. To this condition he applied the name "white pneumonia." Lorain and Robin referred to it as epithelioma of the lung. In white pneumonia the lung is much larger than it is normally, and its surface often shows the impressions of the ribs; part or all of a lobe is usually affected, but even both lungs may be consolidated. The lung is usually of a white or greyish-white color, is heavy, dry, and in stillborn children the affected part is devoid of blood and air. The alveoli are enlarged and filled with masses of cells, and the alveolar walls are thickened. The small bronchi are also filled with these cells, which are usually undergoing fatty degeneration. As a result of capillary pressure, the blood supply to the lung areas affected is greatly diminished in the cases that have lived a short time. Characteristic signs of congenital syphilis elsewhere are usually present, and the baby is usually born before full term.

Interstitial Pneumonia often is associated with pronounced prenatal luetic lesions elsewhere. The life of a child with this condition is not prolonged. The most characteristic features of interstitial pneumonia are a small-celled infiltration of the interalveolar connective-tissue and a marked increase of the interlobular connective-tissue. In some cases the interalveolar strands enclose a network of dilated and tortuous capillaries. There is an increase of connective-tissue around the vessels and bronchi, and the tunica intima of the small arteries is also thickened.

Hocksinger summarizes the morbid processes affecting the lungs of syphilitic children as follows: "(1) A round-celled infiltration and proliferation of the interlobular and interalveolar connective-tissue, originating in the cellular tissue around the bronchi, and leading to marked thickening of the lung; and (2) an isolated perivascular cell proliferation, which begins around the small arteries, and is accompanied by changes in the tunica intima." The lungs of syphilitic children contain an enormous number of the spirochetes of Schaudinn and Hoffman; and these cases are of interest chiefly to the pathologist.

In *acquired syphilis*, the chief pulmonary lesions are (1) Gummata, (2) bronchopneumonia, (3) fibroid induration or chronic interstitial pneumonia and (4) a progressive destructive disease—the so called "syphilitic phthisis."

Gummata in the lungs are similar to gummata elsewhere. They range in size from that of a millet seed to that of a hen's egg; and they occur in all parts of the lung, but most frequently within the substance of the lung near the hilus. In early stages of their development, gummata are grayish red or grayish-white in color, somewhat translucent and have a surrounding zone of congestion. Later these gummata become opaque and somewhat caseous, and have a surrounding envelope of thick fibrous tissue. Occasionally gummata of the lung caseate, and may then empty into a bronchus, thus forming a pulmonary cavity. But usually these gummata tend toward the formation of cicatrical

*Read, by invitation, before the Fulton County, Ga., Medical Society, March 6, 1919.

tissue which causes a shrinkage of the surrounding lung substance as well as a dimpling of the lung surface and the adherent pleural surface. Fowler describes two of the specimens in the museum of Guy's Hospital as follows:

No. 255.—The lower lobe from the left lung of a man, aged twenty-seven, who died from erysipelas of the larynx. The specimen shows at its hinder part, a large yellowish mass partially separated from the surrounding tissue. Smaller nodules are seen in the adjacent lung. The pleura over the gumma is much thickened. Histologically, the nodule consists of fibrous tissue which stains with difficulty. There were many gummata in the liver. With exception of the above lesions and some bronchitis, the lungs were healthy. Suppurating buboes and a chancre on the penis were present.

No. 256.—A portion of lung showing scattered through it several small masses of irregular shape, yellowish in color, and firm on section. The masses are easily separable from the surrounding lung, which is healthy. Histologically, the nodules show a central area of caseous material surrounded by a narrow zone of fibrous tissue in which are many small round cells. The liver contained a single gumma, and was in a condition of diffuse syphilitic hepatitis. There were several small gummata in the testes. From a man, aged thirty-nine, who had suffered from cough and dyspnoea for six months and who was admitted for hepatic ascites and slight jaundice.

Bronchopneumonia is one of the pulmonary manifestations of syphilis. Delepine and Sisley recorded a most remarkable case in which an enormous gumma of the right lobe of the liver, measuring 5½ by 4½ inches in extent, and adherent to the diaphragm, pushed up and extended through the diaphragm and involved the lower lobe of the lung. In addition to sclerotic induration there were patches of lung tissue resembling catarrhal pneumonia and there were patches of caseous pneumonia. This condition resulted from direct extension and surely was not an ordinary bronchopneumonia. Pavlinoff described a bilateral syphilitic bronchopneumonia with patches of consolidation interspersed between areas of normal tissue. The alveoli were filled with desquammated epithelium, leucocytes, and erythrocytes, and the pneumonia patches were dull slate-colored on section.

Fibroid induration or chronic interstitial pneumonia is another type of pulmonary syphilis. An inflammatory reaction follows the lodgment of spirochetes in the lung. This inflammation takes the form of an extensive cellular infiltration, together with an overgrowth of the connective tissue in the interlobar and intralobular septa and a proliferation and desquamation of the alveolar epithelium. The alveolar walls and the blood-vessels become greatly thickened. The result is that long strands of connective tissue which usually radiate from the hilus of the lung and which more or less surround the bronchi and blood-vessels, but which may originate in the pleura, divide the lobes and groups of lobules. In addition, there are frequently patches of sclerosis and diffuse fibrous changes affecting a lobe or even an entire lung.

Syphilitic phthisis is probably the rarest of the luetic lesions in the lungs. This condition is usually the result of a gumma caseating and emptying into a bronchus. In order to be sure of the existence of so-called "syphilitic phthisis," Fowler says the following conditions must be fulfilled: "(*a*) The case must be complete, that is, the symptoms observed during life must be considered in connection with the lesions discovered on post-mortem examination; (*b*) the evidence of syphilitic infection must be undoubted; (*c*) repeated examinations of the sputum must have been made, and tubercle bacilli invariably absent, and the absence of tubercle from the lungs (as the cause of the lesions) must be proved by postmortem examination; and (*d*) syphilitic lesions, about the nature of which there can be no doubt, must be found in other organs." This same author cites, among other cases, the following case as illustrative of this *luetic* consumption:

At the age of eighteen the patient had a sore on the penis, for which he was treated for several months. In 1890, he suffered from cough and expectoration and had an enlarged gland in the inferior triangle of the neck on the right side, dullness at the right apex, with feeble breath sounds, and bronchial breathing in the right supraspinous fossa. The liver was large, nodular, and very tender. He took potassium iodide in gradually increasing doses and obtained some relief. In April, 1893, he noticed edema of the legs and scrotum. He had a troublesome cough, with the expectoration of large quantities of extremely fetid pus. The breath was fetid.

Physical Signs: Expansion deficient on the right side. Relative dullness at right apex, front and back; breath sounds feeble over dull area. Absolute dullness from level of fifth interspace in nipple line and axilla to base; behind from angle of scapula to base. Vocal fremitus and resonance diminished, and breath sounds audible over dull area. Urine, sp. gr. 1004, contained albumin and fatty casts. The expectoration consisted of frothy, greenish pus, forming thick masses in a watery fluid, and did not contain tubercle bacilli. On May 17, the chest was explored in the axillary and submammary region. No pus was found. May 19, the liver was exposed by an incision below costal arch, and a depressed cicatrix seen. The expectoration continued copious, green and fetid. Absolute dullness appeared over the whole of the right side up to the clavicle. June 15, offensive pus was evacuated through a cannula inserted in the third right interspace in the mid-axillary line; a portion of the fourth rib resected, more pus evacuated, and a drainage tube inserted. June 19 and 20, hemorrhage from wound. June 21, death.

Necropsy: Abstract of Notes—Old syphilitic scar in trachea, six rings above the bifurcation; more recent scar at bifurcation producing stenosis of the main bronchi to the right upper and lower lobes. One bronchial gland enlarged. Pleura over right lobe adherent and much thickened. Bronchi much dilated beyond the site of stenosis. At the base of the upper lobe were two large irregular cavities with sinous outlines communicating with large bronchi, lined by a distinct membrane, and containing sloughy portions of lung tissue. The anterior cavity had been opened by the incision. The section of the lung was smooth and presented a finely-speckled yellow appearance. No pus exuded from the yellow spots on pressure. In the anterior part of the lower lobe there was a large irregular cavity, the walls of which showed no signs of any mucuous membrane; these walls were covered with a yellowish-gray sloughy material. No tubercle present and no cascation. The lung puckered in many places and was fibrous throughout. Liver enlarged (76 oz.). Large puckered cicatrix on the upper surface of the left lobe and many similar cicatrices elsewhere. A cretaceous and caseous gumma on the posterior aspects on the right lobe. Liver substance fatty and amyloid. Kidneys were large, pale, lardaceous, and fatty.

In addition to the four types referred to, Landis mentions another form in which the lesions consist of an area of consolidation and catarrh, which may occur around the root of the lung or at one apex. Landis and Lewis have reported six cases in which the physical signs pointed to a focal lesion in the

apex and in which the evidence seemed to be conclusive that a latent syphilitic process was present. May I describe briefly just one of these cases?

A male, aged thirty, was admitted to the White Haven Sanatorium, several years ago, with a history of having been ill for some months. He had lost about twenty-five pounds in weight; he had a cough, expectoration, slight fever, and a marked hoarseness. Examination of the lungs showed impairment of the percussion note, feeble breath sounds and a few fine râles at the left apex. The case seemed to be clearly one of pulmonary and laryngeal tuberculosis. Two weeks after his admission, the trouble in his larynx was found to be specific in nature. Under mixed treatment, he made a complete recovery, the pulmonary signs entirely disappearing.

The *symptoms* of syphilis are not characteristic or distinctive. Coughing is probably the most common symptom—which results from irritation of the respiratory tubes or from changes within the lungs. The coughing usually produces offensive, yellowish or greenish-colored sputum. Hemoptysis also is a common symptom. Sometimes the blood is just sufficient in amount to tinge the sputum, but at other times it is more profuse. Loss of weight and of strength occurs in practically all of the cases. Night-sweats are not infrequent. Dyspnea occurs in some of the cases. Fever is present in many of the cases; often this pyrexia is of the tubercular type.

The *physical signs*, like the symptoms, are neither characteristic nor distinctive. The physical findings are, of course, dependent upon the character of the lung lesion.

The diagnosis of pulmonary syphilis is made by exclusion. Tuberculosis must be ruled out. In order to rule out tuberculosis as the cause of such symptoms as were mentioned, one must resort to every valuable test—especially the staining of sputum which has been digested by sodium hypochlorite, the inoculation of guinea-pigs, and the complement fixation test for tuberculosis. One should not give potassium iodide as a therapeutic test until all other tests have been given negative results. Patients who have syphilis of the lungs may give a syphilitic history; they usually have evidences of syphilis elsewhere than in the lungs; and they practically always have a strongly positive Wassermann. Fowler draws attention to the chief points of difference between the pulmonary lesions of syphilis and tuberculosis as follows:

"1. Tuberculosis usually affects the apex of the lung, and, subsequently, the apex of the lower lobe, and tends to progress along a certain route. The primary lesion of syphilis is often about the root and central part of the lung; the disease follows no definite line of march, and gummata may be found in any position.

"2. Both gummata and tubercles may undergo either necrosis and caseation or fibrous transformation; but with caseous tubercle the tendency toward softening and cavity formation is the rule, whereas a caseous gumma very rarely breaks down.

"3. The progressive destruction of the lung by a process of disintegration leading to a gradual increase in the size of a cavity, a change so commonly observed in tuberculous disease, is rarely, if ever, observed in syphilis, except as a secondary result of stenosis of one of the main bronchi.

"4. In nearly all cases of advanced destruction of the lung occurring in the subjects of syphilis, stenosis either of the trachea or of one of the main bronchi is present, whereas this lesion is very rare indeed in tuberculosis.

"5. The cavities found in cases of pulmonary syphilis are usually bronchiectatic, but not invariably so; whereas, in tuberculosis, they are commonly due to progressive destruction of the lung, but may be bronchiectatic.

"6. The tendency to the formation of pulmonary aneurysms, which is so marked a feature in tuberculosis, is rarely observed in pulmonary syphilis.

"7. Pulmonary lesions in tuberculosis are very common, whereas in syphilis they are extremely rare."

The coexistence of syphilis and tuberculosis in the same lung occurs probably more frequently than we suppose. A long standing syphilitic infection may lower one's bodily resistance so that tuberculosis may easily develop. In such a case the tuberculosis does not differ from that occurring in non-syphilitic individuals. But if the two diseases develop simultaneously or within a short time of each other, the association is especially vicious and usually overwhelms the patient, the tuberculosis running a very rapid course. Distressing examples of this are often seen in young prostitutes who have developed tuberculosis in the early stages of the secondary period of syphilis. In 191 Keilty reported a case of syphilis and tuberculosis in the same lung. The subject was a colored male aged 23 years, who showed a progressive loss of weight, with cough, and a profuse, fetid expectoration of three weeks' duration (seven weeks before death). The physical signs pointed to infiltration and cavity of the lower left lung, with infiltration in the right. In the absence of tubercle bacilli in the sputum, and with a history of a rapid course, diagnosis of pulmonary gangrene led to operation when the tuberculous nature of the case was revealed. At autopsy, syphilis in the form of chronic interstitial pneumonia with bronchiectasis, and tuberculosis in the form of miliary and conglomerate tubercles with caseation were found in the left lung, and tuberculosis almost alone was found in the right lung. Both the tubercle bacillus and the spirocheta pallida were demonstrable in appropriately stained preparations.

The treatment of syphilis of the lungs is the same as the treatment of syphilis in other parts of the body. The best treatment is the prophylactic. Arsphenamine, either intravenously or orally, and the classical mixture of mercury and potassium iodide are our remedial stand-bys. The treatment should be thorough and prolonged.

In the treatment of syphilis, we physicians have a great opportunity to render real humanitarian and life-saving service to the afflicted mortals about us. We may not make this life all poets and weariness a name, as one poet dreamed; but we surely can prevent many of the saddest, never-told tales of blighted lives, ruined homes, and graves of unnamed babes.

THE SPECIAL TREATMENT THAT SHOULD BE GIVEN MILK INTENDED FOR INFANT FEEDING.

BY J. M. W. KITCHEN, M.D., M.S.,
EAST ORANGE, N. J.

INASMUCH as milk is now generally conceded to be of vital national importance as a food, and especially in connection with securing adequate nutrition for the entire growing population; and as a pure supply that is assuredly safe and wholesome is most desirable for all who are consumers of that food, the question may be raised as to why *all* milk should not be so produced and treated as to be good milk. The answer is that adults can usually, temporarily at least, stand up against a poor character in milk that infants as a rule cannot. Of course those of all ages should enjoy the benefits of pure foods; but in the pursuit of "life, liberty, and happiness," many, under the influences of peculiar "kulturs," feel at liberty to subject themselves to chronic poisoning; and the world has not advanced far enough yet to feel warranted in sumptuary interference with the dietary habits of the individual in other matters than alcohol consumption. We have to acknowledge that the peculiar damages done to society by alcohol gives special reason for intervention in that particular case; and if we hold it to be a duty of the individual to do his utmost for the benefit of the State, some other ingestive indulgences also should be prohibited. But as long as consumers think that decayed milk, butter, and cheese are good enough for them, they are not likely to be willing to pay the extra cost of really good milk. I am assured by prominent intelligent milk dealers that it is not the most wealthy classes that are the largest buyers of the "certified" grade as a rule.

When it comes to milk for the babies, the very poorest classes buy it. At a matter of fact, the less affluent classes have been better informed through special community instruction than the wealthier classes. I made a special effort to do a little educational work among my élite women neighbors. One charming simpleton wrote me that she did not want to know anything about the matter, for *her* milk and butter were "delicious." There ought to be some strongly effective natural influence continually at work in weeding out the more foolish units of the race.

Every baby who is brought into this world of struggle ought to be given a square deal, and not be poisoned to death as unnumbered millions have been through the ignorance and indifference of those who have had their feeding in charge. The very best of milk that it is possible to produce should be delivered to the consumer at a cost of not more than two cents a quart over the price that has to be charged for grade B milk. Grade B milk is *not* good enough for anyone, much less for delicate infants or delicate adults. Unmodified cow's milk may be an excellent food for some who have ostrich-like stomachs, or for the calf with its four stomachs, having special power of digestive liquefaction; but if any intelligent person will experiment a little with the coagulative effect of rennet and heat on plain milk and on milk modified by any agent that secures flocculency in the coagulated milk, they ought to see that the leathery, hard lumps of the unmodified milk are unsuitable as food for a delicate infantile stomach.

In this paper I do not propose going deeply into the subject of milk modification. When I consider that no man who has ever lived has had sufficiently expert foresight to prescribe a meal that will surely meet in the best manner the unknown metabolic requirements of the individual in the period immediately succeeding the ingestion of the meal, I begin to think what a guessing problem is up to every pedriatrist when he undertakes the artificial feeding of an infant; and I feel that if I can tell him how a safe and wholesome milk of standard quality as to its nutritive constituents can be secured, I have done *my* duty, and can then let the further burden of duty be borne by him. It is astonishing to consider the dietary practices of even the more intelligent members of the race—practices that unquestionably more or less shorten the lives of every living human being, and usually more than less. It is difficult to control the nutrition even of a baby over whom we have mandatory control, and when one realizes how the available supply of milk for artificial feeding is produced and treated, it is disheartening. No wonder that those who understand the situation are urging mothers to nurse their infants to the extent of their mammary ability. Yet the fact is obvious that with mental evolution and later day civilized methods of life, women degenerate as milk producers. A medical missionary has told me that the wild negro women of Africa are splendid milk producers; that they nurse their children for several years; and that in case of necessity a woman without having had a child may be able to stimulate her breasts into activity and feed orphaned infants.

Many of us still living can remember when we did not know why the bottle-fed babies died as they did. We did not know what caused the atrophic marasmus from which so many died. Hundreds of millions of relatively intelligent individuals still alive do not know yet. Part of these ignoramuses do not believe in the existence of microorganisms. But when the compound microscope was evolved and was used by Pasteur and other men of genius, we had the microorganic world, including the milk-borne bacteria, disclosed to our view. Then sus-

picion was aroused. Suspicion was followed by the clean-milk movement, which was initiated in harmony with our scientific knowledge of that day; but which in view of our present knowledge and our further suspicions, does not go far enough. Individual cows may be seeding whole dairies with tubercle bacilli without being detected. My own herd was largely infected without having shown any outwardly observable symptom. I do not remember now just why I ordered the herd tested, but when I did, one-third reacted, and it took three years of slaughter to free the herd. Yet tuberculosis was my specialty. Personally I do not attribute so much importance to the pathogenic menace of specific germs as I do to the possible bacterial poisons that may and do accumulate in milk. Nevertheless, we should not permit pathogenic bacteria of any kind to be fed to any one.

Healthy cattle, unobjectionable cattle feeds, and cleanliness in production are all excellent factors in securing the best character in milk for infants; but other factors in the way of protection against infection, purification, and preservation should be practised. Many illustrations of disease outbreaks that have been traced to "certified" herds could be cited. Many infections occur that are accidental, unanticipated, and unpreventable. Many infections of individual bottles, during the bottling of the milk, and in the pouring of the milk, must occur. Every individual's hands are hopelessly infected, and, very generally, with intestinal bacteria. The bottle tops are regularly infected by the distributors' filthy hands. Every commercial milk bottle closure now in general use is a bacteria trap; and an avenue of infection of the milk is the bottle. Proliferation of countless numbers of infecting bacteria occurs before pasteurization; and considerable numbers from the undestroyed residue of bacteria and spores that survive pasteurization. No milk now used has all of its volatile putrefactive constituents sufficiently eliminated. This is the kind of milk that most artificially fed babies consume today. Such a situation is a sorry comment on the intelligence of the civilization of the day.

The solution of this problem is largely through an application of temperature influences of sufficient intensity, at right times, and sufficiently prolonged. In addition, milk for babies should be distributed in hermetically sealed containers that also protect the pouring surfaces and closure from infections. All milk should be pasteurized, but no part of babies' milk should be allowed to have contact with heat higher than 150 deg. Fahr., nor longer contact than is needed to secure desirable results. Milk that has been heated to 212 deg. Fahr. can be digested by individual babies having strong gastric organs; but, from what we know, all heating of milk at temperatures above the temperature of the body more or less changes its character. But moderate changes in character appear to be of negligible moment.

Various volatile matters of bacterial putrefactive origin are diffused from the cow's body into the milk at the time of its production. The usual method of coincident aeration and cooling does not get rid of all of such contaminants. A forced elimination by the aid of moderate heat is needed, and, preferably, under the influence of a partial vacuum. Preferably this purification should be done immediately after the production of the milk and before the milk loses its inhibitive power against germinal proliferation; and, preferably, this shall be done by a further heating of the milk while still naturally warm, and through securing a circulation of the milk in aerial exposures in such manner that the volatile matters are driven off and removed by a mechanical exhaust and without allowing any infection of the milk to occur during its purification such as generally does occur during aeration and cooling. The milk should be preheated by low temperature heat, and, if possible, bottled while quite warm; and then, after the container has been hermetically closed, the milk and the container should be subjected to a pasteurization, and then quickly cooled. At all other times the milk should be kept at a temperature so low that practically no fermentation of any kind can occur in it; and at so much lower temperature that there is a reserve source of frigidity in the milk itself to meet and overcome heat absorption from outside atmospheric and other conditions. I am only stating the principles that should be applied. There are various essential details that must be practised, but all of them are easily carried out with simple means.

In securing preservative intensity of temperatures, degrees other than temperatures between 120° Fahr. and 35° Fahr. should be aimed for. Sufficiently low degrees can be secured only by mechanical means, or by ice and salt brine. Iced water is not cold enough; it is rarely cooler than 40 deg. Fahr. However, a can of iced water containing considerable unmelted cracked ice and held in the family ice-chest is a convenient means for holding bottles of babies' milk for the twenty-four hours that some of the supply must be held. Even with certified supplies, a large part of the milk used for babies is not consumed until more than seventy-two hours after its production. Hence non-fermentative temperatures in it should be maintained prior to and up to the time of its delivery to the home of the consumer. Unless the milk is delivered during the day so that it can be immediately iced it should be delivered in closed ice-packed delivery cases. Most modified milk plants have the cases but frequently they do not properly use them. I do not know of one where a fully intensive refrigerative practice is carried into effect.

There appears to have been an unwarrantable degree of apprehension felt as to the possible destruction of enzymes in milk through its heating. There is no evidence in hand going to show that moderate heating does destroy any of the small amounts that may possibly be present. Some writers contend that cow's milk has no enzymes in it and state that the calf has no use for them. The experts of the Bureau of Animal Industry at Washington assure me that if there are any in milk, the effects they produce are so slight that it is perceptible only when the milk is held under favorable conditions for several days, and that the effect therefore is infinitely less than the effect of the digestive juices in the stomach. There is no occasion for heating babies' milk so much as markedly to change its smell, color, taste, and ease of digestion. But enough heat should be applied to pur-

it and render it safe against pathogenic infection. Ninety five per cent. and over of milk bacteria can be destroyed by moderate heating without changes in the milk that could possibly induce scurvy or rickets. Bad milk and overheated milk may possibly be causative of those troubles to some degree, but not good milk that has not been unduly heated. A vast prewar experience in Europe, where they boil their milk, shows that in a nine months' course of artificial feeding, although breast-feeding shows best effects at first, babies are better nourished on boiled cow's milk than by breast-feeding.

In regard to modification, I do not accept the views of those who think that cow's milk is all right if it is only diluted with water. In view of our lack of full information as to the uses for the albuminous principles in the body, we should not be too positive as to the best nutritive requirements of the infant in regard to the protein elements in its food. Nitrogenous matter is the spring of vital action. Without it no life is manifested. We know that it is needed in muscular and other structural developments and their functioning. It is required for secretory purposes, and especially in milk formation. The carnivora and the wild races of man may have to adjust themselves to meat as food because of its availability; but albuminous matters are not absolutely essential to the production of force or to form fat; and the production of urea is only a sequence to prevailing conditions. It is possible that a generous presence of nitrogenous matters in the body may be essential in securing a general stimulative nutritive and functioning effect; but from what we know of the effect on adults of ingesting excessive amounts of proteins, it seems desirable that we should exercise considerable caution in including large amounts of proteins in the food of our infant dependents. Excessive amounts may be expected to result in more acidulous gastric products than the alkaline intestinal juices can neutralize; and possibly such excess may set up more or less putrefactive intestinal activity; both of which results are objectionable. A baby that sleeps most of the time and takes very little muscular exercise certainly does not need a large nitrogenous content in its food, and it can get its force very conveniently from the carbohydrates. But a reasonable nitrogenous supply is of unquestionable importance. There should be a proper proportion of albumin, but not an excess of casein. That special nitrogenous constituent should be modified as to its natural coagulability. At each time of feeding, water, albumin, earthy salts, sugar, and a flocculating constituent can be easily, conveniently, and safely added to a standardized, cream enriched milk that is sufficiently water-free to furnish an adequate concentration of nutriments for a twelve-months'-old child. The precaution needed is that the basic milk is pure and safe. All the modifying agents, other than the cream, can be thoroughly heated without damage to them. But the basic milk cannot be sterilized without injury to it. Dextrinized oatmeal gruel seems to be unequal as a modifier when a laxative effect is desired. Probably some of its specific effect is due to the mechanical action of the large cellulose content that resists dissolution from heat in the making of the modifying gruel. Dextrinized barley has been such a standby for so long a time that it seems almost unfriendly to think that there may be something to take its place that is better; but as the result of some of my research work, I am inclined to think that concentrated whey, if properly prepared, may be better than barley, because the latter, along with oats, has a large content of cellulose detritus.

So far as I am able to judge, concentrated whey flocculates milk as well as or better than barley. Rennet-treated whey and milk resist the hardening effects of unmodified milk coagulation when heated. It is possible that all babies' milk should have more or less of concentrated whey added to it prior to its feeding. Whether the albumin, earthy salts, and milk sugar in milk whey are better than those from cereals, I have no knowledge. Further study in this connection is desirable.

I am against the general use of any of the standardized prepared baby foods if fresh, uninfected, and purified milk with a sufficient amount of butter fat in it can be secured. The growth principle that is in butter fat must always be remembered in the future. However, there are situations in which it is not possible to procure good fresh milk. It is theoretically possible to meet that need partly in a modified dried milk powder, that in conjunction with an intelligent auxiliary modification may be serviceable. But so far I have not examined any entirely satisfactory dried preparation. Deficiency in butter fat content, over-heating, insolubility, objectionable taste, large bacterial content, and quick decomposition after dissolving seem to be usual defects. Most of them have much unconverted starch. But sufficient boiling changes hydrated starch into dextrin. I am undecided as to whether vegetable albumin and casein may successfully replace animal constituents of like nature; but it is certain that the vegetable oils will not supply the growth principle that is in butter fat, and they are not as digestible; this defect in vegetable oils may be due to irritating matters in them, as those which markedly exist in croton, castor, cotton, and other oils. Manufacturers of dry milk powders, so far, have not been able to overcome the decomposition action in butter fat in their preparations when exposed to air, and when held at fermentable temperatures, if largely present.

The race has a big task before it in educating its individual members as to what to eat and what not to eat. It is questionable whether moderate gustatory indulgence for adults should be preached in this connection; but with infants we should be radical in our control, because as trustees we are in honor bound to so act.

94 Prospect Street.

DISEQUILIBRIUM OF MIND AND NERVES IN WAR.

By ARTHUR MAC DONALD,

WASHINGTON, D. C.

HONORARY PRESIDENT OF THE INTERNATIONAL CONGRESS OF CRIMINAL ANTHROPOLOGY OF EUROPE.

Disequilibrium from psychological troubles in war is essentially individual, but it does not necessarily mean insanity; the war seems to have produced a large number of cases in an intermediate zone between insanity and sanity. Soldiers are selected

with much care so far as their physical side is concerned, for they are liable to be exposed to unusual hardships, to exhausting periods in battle maneuvers, to extreme changes in temperature, and to infectious diseases. In 1,072 mental cases in St. Elisabeth's Hospital of Washington, D. C., from 1899 to 1908, the recovery was 57 per cent., while 30 per cent. is a good average in civilian cases. Soldiers show more frequently acute mental diseases of short duration. The hope for recovery is mostly in the early stages, before permanent damage is done to the brain.

Those whose mental troubles arise from the war are not the real insane, and should be distinctly distinguished from those; their mental aberration is due to an emotive shock; they are no more insane than a person whose aberration is due to typhoid fever or pneumonia or uremia or some surgical traumatism. Many of these return to the front. It would be not only an injustice but very foolish to intern such in an insane asylum. Imagine what the effect would be if it were said, "Our commander has just come from the insane asylum."

The soldiers attacked with insanity needed more care than wounded soldiers in the Russo-Japanese war. Estimating the Russian army at one million, there were 350 cases of insanity for every thousand men, 1.9 per cent. insane. In one of the hospitals the officers constituted 21 per cent. and the soldiers 79 per cent.

It is to be noted that slight mental aberrations are observed in the army that are met in civil life. On the other hand, men in the army are specially selected, while civil life is dotted with many defectives. Young men, who are failures in civil life, often join the army in the voluntary service, making it a sort of refuge. As soon as military service becomes compulsory, the mental status of the army improves.

Mental disorders may be caused by the general fatigue of duty, long marches, exposure, loss of sleep, terror, and shock. Where cases are studied carefully, those of malingering are usually few and not important.

Normal War Psychology.—Before entering into further consideration of mental and nervous disequilibrium in warfare it may be well to recall the conditions of normal war psychology.

A man with intellectual tastes may find it difficult at first to only obey and ask no questions, but training gradually overcomes this, and the intellectual will realize the necessity of it, if the squad are to be efficient fighters, obeying orders instinctively; thinking and initiative are not desirable, if not dangerous, for the common soldier. Only officers are allowed to do any thinking. The intellectual man may become an officer, and his difficult experience in learning to obey will now help him to understand better how to make others obey. The private soldier must be taught inhibition; he must yield to strict discipline and suppress and repress all counter wishes, especially the feeling of self-preservation. If he is an intellectual man he will understand the reasons without asking them, and take things philosophically. Such a man is on the road to promotion, and is apt to become an officer, if not leader. Good health and sound body, well developed, give physical and mental equipoise and self-control, and are necessary for every soldier, and the more so the higher his rank.

Conditions Near the Front.—When the soldiers continue training in the rear within the sound of the guns, the discipline is much more severe. Those who have fought in the trenches seem indifferent, and seldom talk of the battle a few miles away. However, the feeling of personal safety is indicated by the word "Blighty," which is a slight wound, necessitating removal to a hospital. The trench men are not only indifferent but are confident and self-possessed, while the men soon to go to the front for the first time are restless and fearful. However, the behavior of those experienced in fighting showing resoluteness and composure, has a good effect on the inexperienced soldiers.

At the front the new soldiers are curious to see the enemy, and they are often reckless; at the least disturbance they man the loopholes and fire everywhere, using more ammunition in a day than veterans do in a month. The first and lasting impression from the trenches is continual movement and great noise; the sensations of heat, cold, pain, and fatigue are secondary to noise. But as man, more than all other animals, is noted for his power of adaptability to environment, the new soldiers soon accommodate themselves to conditions and count the shells, guessing where they will fall, often distinguishing them by the sound. Some are called "Whistling Willows" and others "Black Marias." Some fight the enemy for a month without ever seeing him. Continual danger and constant attention to defense make a soldier hungry. When badly fed, a soldier is liable to lose confidence, grumble, if not revolt. Plenty of food, with tobacco, tends to make him ready for the fray and indifferent to danger. Just as in civil camp life, the meals are the great events of the day. After a battle, at meals the gaps are evident, but yet they are a part of war, and why worry? It is all in a lifetime. The soldier seldom thinks he will be killed; he may receive a slight wound. Danger is present for all, and unites the men, massing them together in a common cause with a leader. It gives them great power for endurance and effectiveness. Officers are almost always superior; in fact, true merit is recognized in war more than anywhere else. Since this was a long war under very different conditions from all previous wars, war psychology will doubtless become an independent branch of study.

After a few days, the soldier's life in the trenches becomes monotonous. The necessary restriction of his movements, the often uncomfortable conditions as cold, wet feet and rheumatism as a result, take his attention, but he must watch, and be ready for anything; yet he adapts himself gradually to almost everything; he becomes indifferent and may be cheerful and contented. He has fear at times; if he is a veteran he confesses it afterwards.

It is said that soldiers in the trenches feel detached and do not think much of home and friends. As to religion, it is estimated that some sixty thousand priests served with the belligerents; yet most of the men seem to become fatalists. There are, however, a few who serve and fight with lofty religious ideals. Also there is little hatred of the enemy manifested, especially among the British soldiers. The soldiers do not delight in killing; the

fighting is impersonal and mechanical; if they don't kill the enemy, he may kill them; both want to get home, but they cannot. Some feel that every one killed may save a comrade. In the bayonette charge soldiers often feel that the more men they kill the less liable they are to be killed, they are not shocked by killing a man, at least at the time.

Heavy artillery has changed warfare work; the contending armies seem somewhat evenly matched, and are seldom put to flight, though repeatedly repulsed. In retreat the men may become discontented, tired, and fatigued through loss of sleep, which becomes so powerful that they sleep while marching, and when tottering too much the soldiers punch them a little to keep them from falling.

It has been said there are four types of soldiers: (1) The muscular, which has a rectangular face, strong symmetrical limbs, constituting about 47 per cent. of the French people, and comes from the country districts. (2) The digestive type has a flat pyramidal head, large digestive apparatus, long body and short legs, and small chest. (3) The respiratory type has a large chest and hexagonal head. (4) The cerebral type has a brachycephalic head, small in figure, supplying only 7 per cent. of the soldiers before the war.

The four types above noted are seldom pure, but more often mixed. Two general classes of soldiers may be contrasted, according to their bringing up in the country or in the city.

Fear.—After this brief statement of normal psychological war conditions, we may note various points and phases of mental disequilibrium, as fever, dreams, simulating, and shellshock emotions.

The bravest soldiers experience fear, but the most of them suppress the expression of fear. Then there are many men with absolutely no taste for war, and when exposed to physical and mental exhaustion, combined with fear, they are suggestible, though in civil life they would not be suggestible. There is a conflict between the instinct of self-preservation and the moral sense. Amidst the roar of shells, such persons may gradually lose their self-control, and if shocked or bruised easily come to believe that they may have some grave disease, and may not be fit to fight any more.

There are certain individuals of limited mental powers who are useful in military service regulated by times of peace, but when war comes, they appear to be wholly incapable to meet the more complicated conditions. Many of these persons are not only abnormal, but sick, and cannot be benefited by repressive methods. They are irresponsible and not adapted to military service.

Sometimes, when new conditions suddenly arise, separating the soldier from comrades, he may have fear; also when isolated. After all, the feeling of fear varies in degree and kind with the individuality of the soldier. The men may suffer from fright when men near them are killed and often shockingly, but they can become accustomed to even this, and be indifferent as to death.

Dreams.—It is mainly since the South African and Russian-Japanese wars that mental troubles of soldiers have been studied. The wounded returning from the front almost always dream, either little or much, of fighting. This is true of those who before did not dream. Certain dreams are natural; others are morbid, which occur only when some reality forces them, when the sleeper veritably lives them. This precipitates a second state of nocturnal somnambulism, going from silent dreams to dreams in action.

The frequency of horrible dreams in shell shock cases indicates that a psychic trauma influences greatly the mind by the thoughts reverting to the terrible experiences, and that the continuous influence on the sub-conscious mind may account partially for terrified vacant expressions, cold blue hands, feeble pulse, respiration, sweats, and tremors.

Nervous Disequilibrium.—In war, or when war is thought near, there is a sort of wildness prevalent in the public mind; everyone seems ready to believe almost anything. People can be made to think that they will soon be invaded by the enemy three thousand miles away. People usually conservative seem to lose their equilibrium. Thus it was published that Russian troops had landed in Scotland, and that the Russian fleet had been captured in the Kiel Canal.

The appearance of nervous and mental troubles in the present war is a result of nervous tension, overwork, fatigue, and especially numerous emotions to which the soldiers have been subject. It also causes apprehension of serious psychopathic disorders in future warfare, due to the intensity of modern explosives. While on the firing line, these disorders are not frequent, yet back of the lines in the rear, in the hospitals, and still further in the interior, mental disorders find a more favorable soil for their development. Most diverse forms appear. If it be said that this war has created nothing new in the psychonervous troubles, it is none the less true that their multiplicity is surprising, especially in France.

Simulation.—Simulation is often used in the army to designate all morbid manifestations, especially nervous ones, where there is no organic lesion. Thus a trembling or deaf soldier is called a simulator. This is not only an error, but often a grave injustice. The real simulation is a voluntary, conscious, determined, and rational act, which is intended to mislead and deceive the judgment of those around. There are different forms of simulation, as an affection provoked, created, exaggerated, or prolonged. Provoked affections, like conjunctivitis (by tobacco), are not in the medical realm. A created simulation is an objective trouble, vicious, motor, or nervous, or subjective phenomena, as pain and troubles, that attract attention, commiseration, or pity. It is a functional trouble, a nervous condition, organic paralysis which the simulator is forced to reproduce, in seeking to conceal his fraud and give it the appearance of reality. This is the most common form of simulation observed in the army, but in this war this kind of simulation was rare.

The simulation by exaggeration is to amplify the symptoms of a real injury in order to deceive. The simulation by prolongation is the worst; it is the voluntary continuation of an attitude or symptom connected with a real alteration, when it has disappeared or is manifestly healed.

The simulator never succeeds in producing a contracture exactly. The movements of the simulator when trembling become less rapid, less regular;

often, believing he is not observed, the simulator ceases altogether to tremble. If it is a simulated muscular contracture, if the member be placed in an inconvenient position, the signs of fatigue become evident and the contraction may cease. It is exactly the reverse when the contracture or trembling is of a psychonervous origin. The simulation is marked by excessive incoherence of manifestations, the reactions do not correspond to the mental state which it is desired to imitate.

The simulations by exaggeration are much more difficult and sometimes impossible to detect, as pains, lumbago, and other subjective conditions; but a prolonged and repeated examination will often succeed in detection.

There are many little ways in which the soldier will try to deceive the physician, to avoid the service, or some duty. There is a natural skepticism as to trouble, with no objective certain cause.

The simulations in the army in times of peace are organic diseases, especially functional troubles, pains, impotencies, paralysis, strictly nervous crises; but seldom do they try to imitate mental troubles, for they fear the asylum almost as much as going to the front; also it is too difficult to simulate insanity. The soldier who simulates always wants to get his liberty and be free from military service. There are fewer guilty deserters than excusable ones.

Trench Environment and Disequilibrium.—Soldiers in trenches and dugouts, exposed to wet, cold, and often to hunger and thirst (from shelling of communication trenches), are dazed by the terrible noise of the guns, disgusted by foul smells and rats, tortured by flies, fleas, bugs, and lice. All these, combined with gruesome scenes of comrades suddenly struck down, mangled, or shattered to pieces, the memories of which are continually recurring, suggested by some little thing, perhaps, but acting as a premonition, may cause dread of coming death or being blown to pieces by a mine or buried alive. These, and other terrible experiences, depress the vital resistance of the nervous system, and may force the strongest to succumb, so that the next shell may bring disaster, as the last straw on an already exhausted nervous system, worn out by trench warfare and the lack of sleep.

Shell Shock Emotions.—One of the fundamental elements in these psychonervous troubles is the emotion from shell shock, but however intense it cannot alone explain the results; nor are these results apparent at the time of the shock, due probably to the painful visceral perturbations, reaction being instinctive rather than voluntary. But when the neuropath is transported out of danger into a quiet place, symptoms appear, as contracture, paralysis, trembling, convulsions, etc.; the instinct of self-preservation no longer prevents their manifestation. But the emotions tend to escape the control of consciousness and to enter the realm of the unconscious or subconscious. But the patient cannot be made to understand this, because he lacks critical power.

Some of the motor troubles are contractions of the hands, feet, and trunk. The place of the injury has nothing to do with the location of the paralysis; also the intensity of the wound has little relation to the intensity of the paralysis; often the most insignificant injuries provoke the most serious paralysis.

There are many who simply through good fortune and friends have been able to adapt themselves to conditions. In military life, fortunate surroundings fail for the most part, and there appear a large number of inferior individuals. In actual fighting, mental diseases rise quickly. Owing to the new methods of warfare, as continued shell fire, the mental damage of war has become great. Twenty per cent. of the discharges are due to "shell shock," which is applied to nervous symptoms exposed to shell fire, that cannot be explained by some obvious physical injury:

1. Where exploding shells cause death without external signs of injury.

2. Neurological symptoms suggesting power of mechanical forces.

3. Familiar symptoms of neurosis in civil life.

4. Weak, nervous symptoms, where men are abnormally sensitive. Thus many soldiers who have not been exposed to battle at all show symptoms of neurosis.

A soldier who bayonets another in the face may develop a hysterical tic in his own face; one bayoneting enemies in the abdomen may have abdominal contractures in himself. Hysterical blindness may follow from seeing horrible sights; hysterical deafness when the cries of the wounded are unbearable. Not only the rising of the feeling of self-preservation, but horror of ghastly sights and yearning for home have great power. For those there is no method of escape except a wound; if severe, the war is over. Being captured is also a relief.

A man buried by a shell crawls out, but on seeing the mangled bodies around him becomes unconscious. This is not due to a physical injury.

The high explosive shell, by the mere explosion and sudden alteration in the atmospheric pressure produces grave effects on the nervous system; this concussion may affect the mind or spinal cord, causing temporary paralysis.

One of the results of high explosives in huge shells, besides direct material injury to the central nervous system, is the moral effect of continued anxious tension of what may happen; this, with the terror from horrible sights of death and destruction tends to exhaust if not shatter the strongest nerves. Of course, any soldier with a previous nervous weakness will succumb easier to the stress of trench warfare.

The great aërial compression from high explosives may be transmitted to the cerebrospinal fluid about the base of the brain, and cause shock to the vital centers, resulting in instantaneous arrest of the functions of the cardiac and respiratory centers causing death. It has been shown that such explosions cause an atmospheric depression of about 35 millimeters of the mercury tube, corresponding to a dynamic pressure of about 10 tons to the square yard. One effect is to liberate air suspended in the blood and transform it into bubbles of gas, which are driven into the capillary vessels, causing instant death.

Some of the results of shell shock are lack of power of sustained attention on account of mental fatigue; rest is imposed by a feeling of weariness and headache. Irresolution and indecision are al

results from shell shock aggravated by insomnia, anxiety and worry, for the soldiers are conscious of their disability, and fear making mistakes. Loss of memory may be complete; loss of power of recognition may follow.

An explosion not more than from 8 to 10 meters distant can cause organic lesions without any wound or contusion of any sort. The anatomical substratum of these invisible causes is microscopic.

The Agony of War.—The agony of war is a disease of civilians in direct relation with a state of war. It seldom appears among soldiers. The symptoms are usually the same; it develops in persons who have loved ones in the army. It is accompanied with insomnia; there are special anxieties, which increase greatly at the least impression from without, as ringing of the doorbell, telephone, delivery of a letter or telegram, when bad news is thought of. The subject looks to see if there is fighting in the sector where the loved one is; this increases the anxiety, insomnia becomes very persistent, the mind becomes unstable, appetite lessens, the patient grows thin.

There are vascular troubles, arterial tension is always lowered; there is exaggeration of the rotulein and reflex achilles; there are changes in the color of the skin, or thorax, abdomen, finger, or soft body parts, sometimes red, sometimes white; in most cases there is an increase in pulse beats.

The agony of war is in direct relation with the military and diplomatic situation; thus it increases with great military action. It is a diseased nervous condition, observed in all great catastrophes, as earthquakes, great fires and epidemics, causing an intense mental shock to the individual. It has been very prevalent in belligerent Europe.

SHOULD HYPNOTISM BE USED TO CORRECT STAMMERING?

By ERNEST TOMPKINS, M.E.,

PASADENA, CAL.

Dr. Clarence G. Godfrey's article in the *Medical Journal of Australia* (reviewed in the Medical Record of December 7, 1918) in favor of the use of hypnotism on stammerers is such a reversal of accepted views that a criticism of his recommendation seems imperative. Chervin, Makuen, Bryant, and practically the whole field discourage the use of hypnotism. Bryant says, "The sufferer may speak well while under the hypnotic spell, but its influence soon passes away and he feels weaker than before." To allow a reversal of this sound conclusion would be decidedly unjust to the public and to the profession, especially when it is comparatively easy to clarify the situation.

In order to be perfectly fair to Dr. Godfrey, let us base the discussion on the facts which he cites. He mentions cases in which stammering "has been revived after years of disappearance" and others (or possibly some of those just mentioned) in which the stammering "after disappearing entirely for some time will return, but always in a less degree." It is the confusing of this temporary disappearance with the alleged "cure" which is at the bottom of most of the chaos which exists in the field of stammering. How easily the confusion can occur is readily seen from consideration of the circumstances which bring about the temporary disappearance.

In order to simplify those circumstances let us number the two elements of stammering; (1) the fear of disability, (2) the misdirected effort. The fear of disability is the result of accumulated memories of speech failure. For instance, I have just been telephoning; but, although I spoke fluently, a vague fear of disability was with me as I went to answer the call. The details of that fear were not present in my mind, but as I sit here writing I can recall many of them. As vividly as if it had happened only yesterday I can hear a crash and a scream; can hear my mother commanding me go to my uncle's house and telephone for a doctor to come and care for the cook's scalded arm; and can feel myself writhing and perspiring at the telephone in

a vain effort to make the doctor understand. I can recall a volume of such incidents, the influence of which brings a speech doubt to my mind every time I see a telephone. But how is it that I can telephone now, whereas I could not telephone formerly? Simply because I have formed the habit of declining to make the misdirected effort which impeded my speech and which intensified the doubt. For a considerable period I declined to telephone at all. Then when I again tried to telephone it was with the resolution that I would have myself excused if I began to make the convulsive speech efforts. The consequence was that, instead of building up speech fear, I was building up speech confidence; and now the confidence so preponderates that I telephone quite readily.

The circumstances of all the speech of the stammerer are essentially the same as those which have just been narrated for telephoning. The fear of speech difficulty (element No. 1) possesses the stammerer in proportion to the extent of time and to the degree in which he has indulged in the impeding efforts (element No. 2). Each further indulgence in the impeding effort intensifies the fear. It would seem from this that the stammerer would progress to muteness; and so he would, *if he was not frequently distracted from his fear.* And here we have the crux of the whole situation. When the fear is allayed the speech is fluent. Temporary allayment may look like cure; but only long continued declination to indulge in the impeding efforts, and persistence in the fluent talking which occurs when the fear is allayed will bring about recovery. And this recovery is so slow for confirmed stammerers that the name "cure" can not properly be applied to it. Indeed, traces of speech doubt will generally remain with the recovered stammerer long after others have forgotten that he ever had an impediment.

Now that we have explained the two elements involved in stammering we may list some of the characteristics of the temporary disappearance which so frequently passes as "cure."

The temporary disappearance is largely under the control of the stammerer. For instance, after I took a certain treatment the man who treated me never heard me stammer again, and he could have said truthfully that to all appearances I was cured. But the fact was that I had relapsed. However, I dreaded so much to admit my relapse that I carefully refrained from indulging in the convulsive efforts whenever I was in his presence. The old speech doubt had revived with increased intensity, but I studiously evaded the words to which that doubt applied. There is overwhelming evidence that most of the reported cures are no more real than was that one of mine.

The temporary disappearance is subject to artificial control. I use the word artificial advisedly, for the artifices to which the stammerer resorts in order to hide his affliction are legion. Some of the artifices are practised on him by others. Anything which allays the speech doubt will produce temporary fluency. Some stammerers, when they desire to speak particularly well, indulge slightly in liquor. The exhilaration caused by the liquor allays the speech doubt and the stammering disappears. Similarly, when a promotion comes to the poor stammering clerk who could not ask for the bread or the sugar at the breakfast table, he rushes home to dinner and announces his good luck fluently and volubly. The disappearance of his impediment is due to the fact that good luck and not speech doubt is uppermost in his mind. Suggestion, in its multitudinous forms, controls stammering even to the degree of total disappearance for a time. Autosuggestion is commonly used. A friend of mine who stammered but who was gradually recovering under the influence of a favorable environment and much determination was flabbergasted one day by the announcement that he had to meet in consultation the head of the great corporation for which he worked. All his speech doubt came back to him with overwhelming force. But he summoned his determination and reasoned that he was made of as superior clay as the head of the concern and would meet him on terms of equality. In this self-assumed attitude of confidence he passed through the interview swimmingly. That great success contributed largely to a real confidence which further contributed to his recovery; whereas, if he had succumbed to his doubts the colossal failure which would have resulted would have intensified his doubts to such an extent as to put him back a long way in his struggle for speech freedom.

From what has just been said it is evident that there can be no difference with Dr. Godfrey as to the relief afforded by hypnotism, for such relief is unquestionably supported by both observation and reason. The only difference is to the extent, rather the permanence, of that relief; and the overwhelming opinion is that, even if some light cases do recover ultimately under the treatment, the benefit to the speech does not offset the undesirability of long submission of the will of the stammerer to the suggestion of another person.

The duration of the temporary disappearance is indefinite. In the cases of recurrence first cited by Dr. Godfrey the disappearance must have extended for years, probably from early youth to the time that the shock of battle revived the impediment. What better evidence is needed of the persistence of the speech doubt; or of the inadvisability of announcing stammering cures? Yet we frequently hear of the instantaneous cure, the "he-never-stammered-again" kind, and the three-week cure is almost indelibly stamped in the popular mind by advertising as mendacious as it is persistent.

It will probably be sufficient to consider two subjects in conclusion, namely an academic one and a practical one. The academic one is the classification of the disorder. Dr. Godfrey rejects neurosis and considers psychosis surely established. In order to avoid any suspicion of bias or dogmatism let us state the conditions and then let whoever wishes to do so draw his conclusions from the conditions. The origin of the disorder is accidental or incidental interference with newly acquired automatic speech. (If the inducing cause is severe even well established speech may be upset, as by the shock of battle.) The continuing cause is the fear of ridicule prompted by the interference. Notice that the interference is purely voluntary; and that the fear being the result of experience, is perfectly logical. Now will someone—anyone—make out of that neurosis, psychosis, or any recognized disease?

The practical subject is to get rid of the disorder

Since the inducing cause increases in intensity with every convulsive effort, it should be evident that those efforts should be prohibited as soon as they appear, that is, in childhood (excepting war shock). At that stage of the disorder no further treatment is needed because the fluent spells which naturally occur will supply sufficient normal speech to dissipate the fear of disability. As long as society rejects this tame and unremunerative remedy in its persistent search for the mythical cure, just so long will this cruel affliction continue; for, although those stammerers who are fortunately situated may recover by the exercise of determination and persistence, the great majority of confirmed stammerers have no chance of recovery under our present organization of society in which the stammerer is forced to talk in order to make a living.

Medicolegal Notes.

Accident and Pre-Existing Disease—Strangulated Hernia.—In a proceeding for compensation under the Indiana statute there was evidence that the injured employee had submitted to a surgical operation for hernia in 1914. Shortly after this he had typhoid fever, which prevented the results of the operation from being entirely satisfactory. He went back to work and was not bothered on account of hernia, but several years after he saw a lump in his side and quit work for a week. On the morning of the accident he lifted a bale of wire weighing about 150 pounds up to a reel about even with his shoulders, when he "suddenly became pained and sick, and unable to work." He went home and called a doctor, who found his condition to be protrusion of the intestine into the hernial sac with resulting intestinal strangulation, which necessitated an immediate surgical operation to save his life. A medical witness for the employer testified in effect that where there is an opening or hernia sac pressure is liable to cause a protrusion; that assuming there was such an opening, and that the employee immediately before the accident lifted a dead weight of 150 pounds to a height of 4 feet, he would say that it was the pressure from lifting that caused the protrusion; that he would have no doubt about it.

On appeal from an award of compensation the employer correctly conceded that where an employee affected with disease receives a personal injury under such circumstances the act in question would entitle him to compensation had there been no disease involved. When such disease is materially hastened to a final culmination by the injury, there may be an award if it is shown that such injury was the result of accident; that in such cases the court will not undertake to measure the degree of disability due respectively to the disease and to the accident, but the consequence of the disease will be attributed solely to the accident.

It was insisted, however, that these propositions of law did not apply here, because the board's finding showed that the employee was afflicted with a disease or disabling physical condition which rendered him susceptible to the injury for which compensation was awarded upon exposure to "some slight incident," either within or outside of the employment, and that in such cases the disease or condition, rather than the accident, will be treated as the cause of the disability. The court said that both the condition and the injury from which the disability resulted in this case—that is, both the hernial sac or aperture and the protrusion and strangulation of the intestine therein—might have been the result of the accident complained of, in which case liability for compensation could not be disputed. However, under the board's finding, the condition, viz., the existence of the hernial sac, was present before the accident occurred; but the disability upon which the award was predicated resulted from the protrusion of the intestine into the sac and the resulting intestinal strangulation. The board expressly found that the protruding of the intestine into the hernial sac with the resulting strangulation was caused by the lifting of the bale of wire.

The Indiana court affirmed the award, holding that the mere fact that the claimant's condition made him more susceptible to the particular injury which resulted in his disability furnished no ground for holding that the disease or condition, rather than the accident, was the proximate cause of the injury. It recognized that there is a line of compensation cases in other jurisdictions which give to the word "accident," used in the respective compensation acts, a restricted meaning which in a measure justified the employer's contention; but it thought the weight of authority and the better reason favor the adoption of the popular meaning of the word, which includes "any unlooked-for mishap or untoward event not expected or designed."—Puritan Bed Spring Co. v. Wolfe, Indiana Appellate Court, 120 N. E., 417.

Accident—"Poison Voluntarily or Involuntarily Taken"—In an action on an accident insurance policy exempting the insurance company from liability where death results from "poison voluntarily or involuntarily taken, administered, absorbed, or inhaled" the case was tried, on a second appeal (the first having resulted in reversal of judgment for the defendant), upon an agreed statement of facts. The insured, on January 16, 1912, went to a drug store owned and conducted by a regularly licensed and practising physician and surgeon, and stated to him that he was still suffering from a bowel trouble, for the alleviation of which he had previously obtained Squibb's Cholera Mixture, and requested the doctor to mix him up a "hot one," by which the doctor understood him to mean a strong dose of Squibb's Cholera Mixture. The mixture was poured by the druggist into a graduate, from which it was drunk by the deceased. It was stipulated that Squibb's Cholera Mixture did not contain strychnine, or other drug producing the effect thereof, but that it did contain tincture of opium and chlorofrom, both of which are poisonous. In less than an hour after taking the mixture, the insured went into convulsions and died. It was conceded his death was due to poison received in the mixture. The presence of strychnine in the mixture was not accounted for.

Many different clauses in policies providing indemnity for accidental death have been considered by the courts of last resort, but the language used in the exception above quoted appears to have been considered in but few cases. The Supreme Court of Illinois, in Travelers' Ins. Co. v. Dunlap, 160 Ill. 642, 43 N. E. 765, in considering a clause in an accident policy providing exemption for liability in case death resulted "wholly or partly, directly or indirectly from . . . taking poison, contact, with poisonous substances, inhaling gas," etc., held that this language referred to death from poison voluntarily or intentionally taken, and did not include a case where death resulted from accidental poisoning. Other cases are in harmony with this decision, but the language of the policy involved in none of them was identical with that in the case at bar. The basis for the holding in each of this line of cases is that the clause excepting the insurer from liability was designed to cover only cases where the poison was consciously or voluntarily taken. Nothing is contained in any of them to indicate that the conclusion would not have been different if the clause had specifically exempted the insurer from liability for death resulting from poison voluntarily or involuntarily taken.

The court said the deceased could not have intended to take a fatal dose of strychnine. He did not voluntarily do so. Its presence in the mixture was unknown to him. There was no exercise of the volition or will in the act of taking the poison, except in so far as it was a necessary part of the taking of the concoction. The poison was taken independently of his will or volition, and therefore involuntarily. Thus contrasted, the language employed in the exception contained in the policy is given its usual and necessary meaning. "We cannot therefore escape the conclusion that the poison contained in the mixture and which caused the death of deceased was involuntarily taken by him, and that the facts bring the case clearly within the exception of the policy, and that no recovery can be had thereon."—Riley v. Inter-State Business Men's Acc. Assn., Iowa Supreme Court, 169 N. W. 448.

Medical and Surgical Lessons of the War.

WAR WOUNDS OF THE GENITOURINARY ORGANS.

By GEORGES LUYS, M.D.,

PARIS, FRANCE.

MÉDECIN MAJOR DE PREMIÈRE CLASSE; PHYSICIAN-IN-CHIEF OF THE UROLOGICAL SERVICE OF THE MILITARY HOSPITAL DOMINIQUE LARREY, VERSAILLES.

SOLDIERS wounded by war projectiles in the region of the genitourinary organs are first directed, like all other patients, toward the "aid-post," a sanitary formation near the firing line, from which the evacuation of the wounded must take place as rapidly as possible on account of the enormous influx of cases at the time of attacks.

The treatment of wounds of the urinary organs can be carried out only in sanitary formations far removed from the firing line, and prepared to receive serious cases. These patients are then transferred either to a surgical automobile ambulance, or to a large hospital in a near-by town. Some days later, when the patient is out of danger, he is evacuated to a urological center in the interior.

Having created four such centers, in Dôle, Besançon, Amiens, and Versailles, I have had the opportunity of treating a large number of these war wounds, and it is upon the experience thus gained that the present article is based.

We will take up in order: (1) Wounds of the urethra; (2) Wounds of the bladder; (3) Wounds of the kidney; (4) Wounds of the testicle.

I. WOUNDS OF THE URETHRA.

Wounds of the urethra may be more or less extensive, according as they are produced by shell splinters, which cause considerable destruction, or bullets, which may give rise to much less serious wounds.

I have observed seton a wound of the penis, a bullet having passed straight through the penis at the level of the glans while the soldier was in a stooping position. This wound had hardly any bad results, and the patient made a very prompt recovery.

In other cases, wounds of the urethra are much more considerable, often destroying several centimeters in length of the canal. A distinction must then be made between the immediate treatment and the secondary treatment.

When the patient arrives with extensive damage, and there is difficulty of urination, the first thing to be done in such a case is undoubtedly the deviation of the urine by the hypogastric section. This is a rule which must never be disregarded, for whenever it was not followed the sufferings of the wounded were greatly prolonged, even if their condition was not actually aggravated.

The hypogastric incision, in cases of wounds of the urethra, presents the following advantages: (1) It prevents the urine from reaching the infected focus, thus permitting a more rapid cicatrization of the wound. (2) It protects the patient against continued suffering at the time of micturition. The condition of all patients treated in this way has been rapidly improved. The supplementary treatment of these urethral wounds should not be carried out until considerably later, when the wound has almost completely healed and the fibrous and cicatricial tissues have become more flexible. Whatever repair of the urethra may be necessary should now be undertaken, advantage being taken of the preceding hypogastric section. In consequence of the preliminary deviation of the urine, all plastic operations now performed on the urethra are successful in much larger proportion than if a permanent catheter had to be utilized.

As regards the operative procedure which I have always found most successful for the radical cure of pubic or scrotal fistulas following war wounds, the method of Duplay undoubtedly offers the best security. The extensive liberation of the margins of the fistula, followed by secondary fixation with silver wire, yields very noteworthy results. The flaps are not pulled upon, their vitality is not diminished, they are neither cut nor torn by the sutures.

The other methods which have been advocated for urethral fistulas following wounds due to war injuries are: *Cutaneous inversion*, in which the margins of the fistula, after having been freed and turned down like a collar, are everted inward and a second suture is applied above the first. This inversion method seems to yield favorable results only in cases of small fistulas. The other procedures, in the form of *autoplasties with flaps*, or *transplantation of the mucosa*, may likewise be employed in suitable cases.

In the course of these autoplastic procedures it is advisable to be very guarded from the viewpoint of intraurethral manipulations. If a permanent catheter is applied, the wound of autoplastic repair is practically certain to suppurate, and healing is endangered. For this reason, unless a hypogastric section has been previously made for the deviation of the urine, it is recommended not to leave the catheter *in situ*, but to resort to intermittent vesical catheterization (four or five times in 24 hours).

Under all circumstances, and when the operative procedures have led to closure of the urethra, it will be necessary later on to restore the caliber of the canal by means of gradual systematic dilatations with sounds.

In cases with extensive loss of urethral substance several plastic operations will certainly be required, the interval between which should usually be quite long.

The urethral wounds so far discussed concern only wounds of the penile or scrotal urethra. Wounds of the deep urethra are entitled to special attention, being much more difficult to heal.

Wounds of the deep urethra are more difficult to cure and require multiple interventions. The best attitude to be observed at first, in the presence of a wound of the deep urethra, is to effect a deviation of the urine by the suprapubic route. Exceptionally, when grave concomitant lesions of the intestine are present, a colostomy for the purpose of deviating the feces may be indicated, but this indication is altogether exceptional. I have found an occasion to apply it during the entire duration of the war, for the wounds of the rectum, which were observed with some frequency in association with

wounds of the deep urethra, usually healed of their own accord, without intervention.

The subsequent treatment of wounds of the deep urethra is much more complicated, but must as a rule not be undertaken in these as in the preceding cases, unless a hypogastric incision has permitted the deviation of the urine, thereby providing the possibility of attacking the urethrorectal fistula under more favorable conditions.

Various procedures have been advocated for the cure of this urethrorectal fistula; the most simple consisting in the liberation of the rectum from the deep urethra through a long perineal incision, followed by separate suture of the urethral gap and the rectal gap.

Another procedure consists in lowering the rectum so as to make possible a complete separation of the fistulous rectal segment, then shifting the rectal wall as a whole in such a way that only a perfectly healthy portion of the rectum comes to lie opposite the urethral gap.

Finally, a last and most interesting operation, proposed by Professor Rochet of Lyons, is the ischiopubic separation of the insertion of the middle perineal aponeurosis, in order to gain access to the wounded deep urethra. This operation has the advantage of permitting the destruction of the urethral adhesions following the rather common fractures observed in the course of these wounds, more particularly fractures of the ascending ramus of the ischium. It offers the additional advantage of replacing the canal in the axis of the anterior urethra and of exposing sequestra or foreign bodies behind the ramus of the ischium.

I have seen four patients with wounds of the deep urethra, treatment proving successful in only two of these cases. A case which received special attention concerned a patient with a urethrorectal fistula situated very close to the membranous portion of the urethra. The fistula had been located, not only in the urethra by the urethroscope, but also in the rectum by the proctoscope. Four operations were performed: twice, simple suture of the urethral opening combined with separate suture of the wound in the rectum proved unsuccessful. Two other times, lowering of the rectum even combined with resection of the rectal fistula yielded no good result. The patient, worn out by all these operations, finally remained in about the same condition as before, urinating in part through the canal and in part through the rectum.

In another patient with complete destruction of the anus and of the prostatic urethra, hypogastric section was first made and maintained for a long time, then in a later operation a curtain of rectal mucosa was lowered to cover the gap in the prostatic urethra, according to the method indicated by Professor Gayet of Lyons. This patient had a fairly good result and was enabled to leave the hospital after his urethra had been dilated with curved Béniqué sounds. He passed practically no urine by the rectum. As the anus had been very extensively damaged practically no sphincteric fibers were left; nevertheless there was no incontinence of feces.

In conclusion it must be admitted that these urethrorectal wounds cause lesions which are very rebellious to treatment, their cure being exceedingly difficult to accomplish.

II. WOUNDS OF THE BLADDER.

Among the wounds of the genitourinary organs, those of the bladder are with those of the urethra the most frequently observed. Vesical wounds are met with either associated with lesions of the neighboring organs or separately.

Associated bladder wounds are almost invariably combined with fractures of the bony pelvic girdle, more particularly fractures of the pubis, or with intestinal perforations; and in these cases the wound in the bladder is merely secondary, for the peritonitic symptoms which accompany intestinal injuries create such an alarming condition that the vesical lesions are relegated to the background. In other cases, the intestinal injuries are much less serious and the patients may survive. Adhesions develop and the patient may void his urine through points at a great distance from the bladder. Of three patients under my observation, one passed nearly all his urine through an opening in the upper part of the right thigh, and the two others passed their urine through an orifice situated on the posterior aspect of the buttock.

Wounds of the bladder may sometimes remain undetected, and they should be very carefully looked for. Thus, when a patient complains of having had no natural micturition, while a catheter introduced through the urethra shows the bladder to be perfectly empty, and at the same time there is a suprapubic swelling, there is reason to assume the presence of a vesical lesion, and in this case immediate intervention becomes imperative. Hypogastric section should be performed at once as offering the only prospect of a successful outcome for the patient.

The most important rule for the guidance of the operator in the treatment of the bladder wounds through war injuries is primarily the *absolute necessity* to insure a good drainage of the urine, first by freely exposing the wound and next by securing easy evacuation of the urine through vesical drainage. This also adds to the patient's comfort by preventing wetting of the bed.

The diagnosis of a wound of the bladder having been established, it is necessary in the first place to locate the opening into the bladder so as to introduce a drainage tube which guarantees the complete evacuation of the urine. It does not suffice, however, simply to insert a drainage tube into the wound, but we should assure ourselves that it is properly introduced into the bladder itself. In order to comply with this imperative indication, surgical intervention is usually required, with free exposure of the wound under local anesthesia, so as to ascertain that the drainage is thoroughly established.

After a good vesical drainage has been allowed to exert its effect for a fairly considerable time (often a month or two), the borders of the wound may be seen gradually contracting, the suppurating tracts drying up, and the perivesical fistulas closing, while the neighboring wounds heal. It now becomes easy to reestablish the normal course of the urine by means of a properly functioning permanent catheter.

Primary suture of a bladder wound seems to be hardly ever practicable in cases of war injury, on account of the associated lesions. Drainage is all

that is left to do, the best drainage being by the anterior median route. Wounds of the lateral walls of the bladder do not necessarily call for a median cystotomy; the surgical treatment of the entrance wound and its tract guarantees a sufficient drainage in the majority of the cases; the later application of a permanent catheter will facilitate the closure of the urinary fistula.

Among the observations collected by the author, the following represents, as it were, the most ordinary conditions in the course of perforations of the bladder:

Private J. H., 26 years of age, was wounded on Aug. 10, 1914, at Burnhaupt, by a bullet which entered at the upper portion of the left buttock, three fingers' width to the left of the crest of the gluteal fold, perforating the rectum and the bladder, and fracturing the pubis. On his admission to the hospital he was found to pass urine by the rectum and gas and fecal matter through the wound of entrance of the bullet. Three days later the patient was catheterized and cystostomy was performed. The urine escaped through the hypogastric incision, a considerable amount also escaping through the rectum; the patient passed nothing through the penis. At the end of three weeks, a permanent catheter was tried but could not be tolerated. Ten days later the cystostomy incision was enlarged and a large drain was applied. After these several operations the wound of entrance closed entirely.

On Sept. 20 the findings were as follows: The wound of entrance of the bullet was closed. The urine no longer escaped through the rectum, but was all evacuated through the hypogastric opening, not a drop passing through the urethra. A permanent catheter was now introduced and vesical irrigations were regularly carried out. But some days later, pus collected at the external angle of Scarpa's triangle on the right side and at the end of fifteen days it was found necessary to make two parallel incisions along the internal aspect of the right thigh. On injecting water into the drains placed in these incisions a communication was found to exist between the right femoral lesion and the bladder, water injected through the thigh returning through the hypogastric opening. There existed, therefore, at this time a double vesical perforation, the first establishing a communication between the right thigh and the bladder through the obturator foramen; the second being represented by the hypogastric opening. An effort was now made to insert a catheter into the urethra, but this was found to be absolutely impossible. A catheter was then introduced through the hypogastric opening and the urethra was entered from behind. The catheter was left in place and daily irrigations of the bladder were carried out. On March 4 a new permanent catheter was passed through the natural passages. Under its influence the vesical capacity gradually increased, rising in two weeks from 20 to 80 grams, and the two perforations of the bladder progressively closed. Early in May the bladder was completely closed. However, the patient constantly complained of passing fecal matter and gas through a rectal fistula. In order to verify the actual existence of a rectal fistula, proctoscopy was performed on May 13, and the fistula was plainly visible on the anterior wall of the rectum. Its exact location was ascertained and when a grooved catheter was introduced into the fistula it was distinctly seen in the rectum. An operation for the purpose of closing the rectal fistula was performed on May 22 with the assistance of Dr. Senn. After a triangular lance-shaped incision, at the level of the fistula, the superficial parts were freed, followed by exposure and resection of the coccyx. A quantity of fibrous tissue was reached, which completely surrounded the posterior rectal wall. The latter was next freed from the fibrous tissue, and the rectal mucosa, which had previously been dissected up, was sutured with catgut. Above this suture two other tiers of sutures were applied, a pledget of iodoform gauze was placed at the level of the coccyx, and a small drain was inserted in the opposite angle of the wound. Horse-hair suture of the wound ("crin de Florence"). The stitches were removed on May 31. A week later, June 8, the wound in the lumbar region was completely cicatrized. But although all was now well on the part of the bladder and rectum, there still remained a small oozing fistula in the right pubic region. Therefore, on June 12, by means of a new operation, several large splinters from the pubic fracture were removed. On July 13 two minute fistulas persisted on the side of the coccyx, through which still oozed some purulent matter and intestinal gases. The urinary fistulas were completely closed. On July 17 a grooved sound passed into the wound of the buttock, through which the patient passed gas, could not be made to enter the rectum. A few drops of a concentrated silver nitrate solution were now injected into the small fistula, and the procedure was repeated several times at intervals of a few days. On Aug. 5 the fistulas were completely closed, and the patient left the hospital cured, on convalescent leave.

In a general way, it may be said that the prognosis of bladder wounds due to war injuries is far from gloomy; and that, provided good urinary drainage has been secured, recovery will follow—after considerable time, but almost with certainty in the vast majority of the cases.

Among the complications which may be observed in the course of gunshot injuries of the bladder is the presence of bony splinters due to fractures of the pelvis, which enter the bladder, and, after this has become closed, may form the nuclei of vesical calculi.

A very interesting case of this kind was observed in a Senegal trooper, 18 years of age, who on June 4, 1918, suffered an extensive rupture of the bladder with perforation of the rectum, caused by a shell splinter. The wound of entrance was at the level of the left horizontal ramus of the pubis and that of exit was situated in the right buttock. The shell splinter had opened the bladder, shattered the pubis, divided the left spermatic cord, ruptured the left testicle, and perforated the rectum, which resulted in the escape of fecal matter through the wound in the buttock.

The wall of the pubic fistula had been cleansed in the first place from all gangrenous masses and pubic bone-splinters had been removed. A permanent catheter No. 20 had been fixed in the urethra; two drains had been placed in the bladder and another drain in the space of Retzius. The patient's local condition had very rapidly improved under the influence of this treatment, and some time afterwards, the radical cure of the now considerably retracted vesical fistula could be performed. In the following September the patient was enabled to get up, and he urinated spontaneously. Soon afterwards, however, he began to complain of dysuria and pain at the level of the penoscrotal angle. On urethral palpation a thickened induration could be felt at this point. A metal catheter was arrested here by a hard substance which gave a sensation of "choc."

A urethroscopic tube was now inserted and the bone splinter was pushed back into the bladder, where it could be seized with forceps introduced through the tube; it was then drawn out in railway train fashion together with the urethroscopic tube.* This bone splinter measured 2 centimeters in length by 1 centimeter in width, with extremely sharp points. The same treatment had to be carried out in this case on two other occasions, so that three bone-splinters of pubic origin were thus extracted through the natural passages.

Extraction Through the Natural Passages of Projectiles Which Have Penetrated Into the Bladder.—The arrest of projectiles in the interior of the bladder is relatively rare, for multiple associated conditions must be realized for a bullet coming from a distance to arrive with the reduced velocity a

*For the technique of all these manipulations, s Luys' "Traité de Cystoscopie et d'Urethroscopie," Par 1914.

projectile force required for its penetration into the small pelvis and its final landing precisely in the bladder. Only a combination of exceptional circumstances permits the observation of similar cases, for, as a rule, projectiles pass directly through the bladder, perforating its walls and frequently also those of the rectum as well.

In view of the fact, however, that simple penetration of a bullet into the bladder has once occurred in one very clearly defined instance, it is permissible to assume that other similar observations might be collected. The dangers threatened by foreign bodies left behind in the bladder are well known; these bodies invariably become incrusted with lime salts and serve as nuclei for vesical calculi.

Aside from such considerations, the question arises what should be done for the extraction of a foreign body which has penetrated into the bladder? In the first place, its presence in the bladder must be ascertained, and contact with it be attempted either by means of an ordinary explorer or a metal sound; or better still, one should try to see it directly with a cystoscope.

The extraction of the foreign body is more difficult, however. When it is small, lithotrites may be utilized. Although small foreign bodies, chiefly hard, have been occasionally successfully extracted with these instruments, it is nevertheless true that the grasping of these bodies between the branches of the lithotrite is attended with considerable difficulty. In the case of an irregular, trabeculated bladder, it is a difficult matter to differentiate the grasping of the wall or of a vesical trabeculum from the hold on a foreign body. Moreover, the practically constant position assumed by the long and rigid foreign bodies in the bladder corresponds, for those whose length does not exceed 7 to 8 centimeters, to the transverse diameter of the bladder, the only diameter which does not vary according to the state of fullness or emptiness of the viscus. A mere grasping of these foreign bodies cannot effect their extraction, for all blind manipulations are insufficient to attain this end, and obviously visual control alone permits a rapid, reliable, and effective seizure and withdrawal.

In the past, when these simple measures proved unsuccessful, there remained only the last resort of opening the bladder by hypogastric section; but one must concede that this operation, although harmless in skilled hands, is here out of proportion to the gravity of the trouble.

The author's "direct-vision cystoscope" (see Luys' Traité de Cystoscopie et d'Urethroscopie, 1914) seems to be destined to become a valuable adjuvant in the extraction of foreign bodies from the bladder. It permits a distinct view of the foreign body, its accurate localization, its efficient seizure under the control of the eye, and its rapid extraction. This was the course of events in the following case:

Private François, 33 years of age, of the 41st batallion of infantry at Cirey-sur-Vesouze, was wounded on Nov. 17, 1914, while in the recumbent position for shooting, by a bullet from a gun discharged obliquely and at an approximate distance of one thousand meters, striking in the center of the right buttock. Immediately after this injury he was able to walk a distance of 4 kilometers (2½ miles) supported by two comrades, to the Bresmenil ambulance, where he had to be catheterized on account of complete urinary retention. Bloody urine was withdrawn by the catheter and for five days it was passed spontaneously. Bloody stools were also observed during two days. The patient was first evacuated to the Baccarat hospital where he remained from Nov. 17 to Dec. 16; while he was under treatment in this sanitary formation the following very characteristic symptom of foreign bodies in the bladder was noted on several occasions. When he endeavored to urinate, and especially at the time of defecation, the urinary stream was suddenly cut off; and in order to permit continued micturition catheterization was necessary for the purpose of pushing the foreign body which was lodged in the posterior urethra into the bladder.

On his next evacuation to the Auxiliary Hospital No. 104, in Dôle, on Dec. 17, 1914, the patient presented three very characteristic symptoms, suggestive of the probable existence of a foreign body in the bladder; namely: (1) Absolute impossibility of urinating in the upright position, micturition being possible only while recumbent; (2) Sudden arrest of the urinary stream during micturition, with pains radiating to the extremity of the penis; (3) Sometimes, as a result of straining at stool, the foreign body became lodged in the urethral canal, but readily returned to the bladder through simple elevation of the pelvis. No symptom of cystitis was demonstrable, the urine being merely slightly turbid when passed. Catheterization of the urethra, performed with a soft catheter, did not reveal the presence of any foreign body in the urethra. The wound of entrance of the bullet was situated in the center of the right buttock, where it presented a small completely cicatrized orifice, ½ centimeter in diameter. A radiogram, taken on Dec. 18 by M. Blandin, showed very clearly a bullet situated in the median line; it was exactly vertical, with the point turned downwards, and retrosymphyseal. The radiograph showed no trace of fracture or of perforation of the ileum, rendering it highly probable that the bullet had passed through the great sciatic notch. The performance of "prismatic" cystoscopy on Dec. 19 showed the presence of a rifle bullet in the bladder. This bullet occupied the right lateral portion of the bladder, resting in a bed-like depression of the vesical mucosa; the point was directed to the left and downward behind the level of the ureters; it was bright and glistening, apparently not incrusted with salts. Under these conditions, in view of the positive presence of a bullet in the bladder, the extraction of the projectile became urgent and indispensable and was accomplished successfully by means of the author's direct-vision cystoscope.

Operation, Jan. 2, 1915. The urine being clear, and after passing a curved Béniqué, No. 59, the bladder was completely emptied. The patient was then placed in a sharply inclined position and the Luys direct vision cystoscope No. 29½ (Charrière) was introduced into the bladder. The mandrin having been withdrawn and the lamp placed in position, it was found that the bladder of the rather stout patient did not readily unfold. However, under the influence of vertical drawing on the abdominal wall by an assistant, the unfolding of the bladder could be observed to take place under excellent conditions. The bullet was at first in plain view with its base forward, but by means of long claw forceps placed in the interior of the cystoscopic tube, it was rotated and its tip after having been turned into the lumen of the cystoscope tube was firmly grasped in the teeth of the endoscope forceps. The lamp of the cystoscope was now withdrawn, and then the patient's inclined position being changed to a horizontal one, the tube was gradually withdrawn from the urethra, holding in its interior the bullet which was half embedded and held by the claws of the endourethral forceps. The bullet was now set in the lumen of the tube, surpassing the diameter of the same by only a few millimeters; it was held in place by friction of its grooves on the walls of the tube, and was withdrawn after the fashion of a railroad train. When the tube had been removed from the urethra, the bullet was easily extracted by means of claw forceps. Irrigation of the bladder was now made with a silver nitrate solution. The operation lasted eight minutes and was done without general or local anesthesia.

The examination of the bullet withdrawn from the bladder by the endourethral route showed it to be an

undeformed German rifle bullet. Its color was grayish black throughout, except at its anterior half, where glistening grooves caused by the jaws of the forceps were seen. The grooves in the bullet contained scanty lime salt concretions, encroaching in no way on the smooth surface. These concretions were of slight thickness and rather friable. The base of the projectile was free from all concretions.

Summarizing, we may say that by means of the direct-vision cystoscope the foreign body was easily and rapidly withdrawn from the bladder, so that the patient was spared the surgical opening of the bladder through hypogastric section.

Another observation, very similar to the preceding, concerns a soldier who had been wounded on October 14, 1914, in the Apremont forest, several shell splinters entering at the level of the bladder. When he was transported to the Besançon Military Hospital, seven shell splinters were removed from his buttocks, but in view of the difficulties experienced by him on urinating he was sent to my Urological Service. Exploration of the urethra showed at once that the lumen of the canal was considerably retracted, admitting only a filiform bougie; on the right lateral portion of the penoscrotal angle there was a tumor the size of a large cherry. The performance of urethroscopy later on showed the presence of a calculus encased in the lower wall of the urethra, at the level of the penoscrotal angle. This was of a distinctly white coloration, interspersed with a few black spots, suggesting a mulberry calculus. Several attempts were made to grasp the calculus with forceps and guide it toward the urethral opening, and finally we seemed more successful, and the tube was gently withdrawn, but just as the foreign body was apparently about to emerge the forceps slipped, the calculus escaped and disappeared. A second insertion of the urethroscope immediately afterward failed, to my great surprise, to reveal the calculus in its former location, at the penoscrotal angle. But as the swelling at this point had decreased it was assumed that the calculus had escaped into the bladder. Therefore, cystoscopy was at once performed, and the calculus was found at the fundus of the bladder; its diameter was estimated to be 1½ cm. It was quite uniformly white in color and seemed to be rounded. As its volume apparently exceeded the normal dimensions of the urethra, lithotrity was decided upon. This operation was attempted on April 28, 1915. After 24 hours' permanent catheterization, the lithotrite was introduced with ease, but when a good grip of the calculus was obtained between the jaws of the lithotrite, I found that in spite of considerable muscular efforts, the calculus was not fractured. A second grip under the same conditions likewise failed, and then suddenly the jaws of the instrument locked and refused to come apart. The situation thus became somewhat embarrassing, but fortunately the jaws of the lithotrite unlocked after a little manipulation, and the calculus dropped back into the bladder. The performance of cystoscopy immediately afterward showed the remarkable and unexpected fact that the lithotrite had scraped off the entire external white coating, which was composed of salts, leaving a blackish mass, evidently metallic in character, and undoubtedly a shell splinter.

Two methods of extraction now entered into consideration—either hypogastric section or an attempt at extraction through the natural passages. The latter method was decided upon, and was carried out most successfully in the presence of several physicians from the St. Jacques Hospital. The patient, having been placed in a sharply inclined position, the Luys direct-vision cystoscope was introduced, and the calculus, which was plainly visible in the vesical cavity, was at once grasped in the jaws of forceps passed through the cystoscope, and the strongly gripped shell splinter was immediately withdrawn, at the same time as the cystoscope.

III. WOUNDS OF THE KIDNEY.

Gunshot wounds of the kidney are relatively not very common. They may be associated with lesions of other organs or be limited to the kidney.

In the former case, *when the kidney is only incidentally damaged by a projectile, the injuries involving other abdominal organs as well,* the performance of a lateral or median laparotomy becomes imperative in order to carry out the operative measures indicated by the lesions present. The following case is of unusual interest:

The patient was a soldier who had been struck by a projectile in the region of the left flank. He presented, in addition to hematuria, a bad general condition, and symptoms of suffocation which attracted special attention. An exploratory puncture made in one of the left intercostal spaces brought only a little blood, but immediately after the puncture the patient collapsed and died suddenly. The autopsy showed the presence of extensive lesions, characterized in the first place by rupture of the upper pole of the kidney, next by perforation of the diaphragm, through which the herniated spleen projected into the interior of the thoracic cavity. These various lesions were hidden by large hematomas.

In those cases where the renal wound is limited to the kidney a distinction must be made between several varieties. In the first place, there are very mild cases, in which the projectile has passed through the kidney without causing any permanent damage. The following case is offered in illustration:

A young soldier was wounded in 1914 by a bullet which had passed through the kidney, giving rise to hematuria, which rapidly subsided under the influence of rest alone. Having the opportunity of examining this man four years later, I found in the region of the right kidney two cicatrices, one anterior, the other posterior, evidently the wounds of entrance and exit of a rifle ball. Examination of the separate urine from the right kidney showed function of the latter to be perfect, and not notably different from that of the left kidney.

The kidney accordingly behaves like the other organs, the lung, for example, in which a bullet may pass through the organ without causing any appreciable permanent lesions. Hence, when there is reason to suspect a wound of the kidney, in the course of a war-traumatism, expectant measures are in order before interfering, and in favorable cases the originally profuse hematuria will be seen to subside progressively. However, in the presence of a voluminous perineal hematuria, indicated by a thickening in the lumbar region, a radiograph should be taken, and if the presence of a foreign body is discovered intervention is indicated.

A case of this kind came under my observation at Amiens. A patient who had been wounded by a shell splinter in the right renal region, presented some time afterward a well-marked thickening of the lumbar region, and radiography showed a shell splinter in the region of the kidney. A long lateral lumbar incision was made, but in spite of the radiographic localization of the projectile, the foreign body was not found at once. The patient had to be placed upon a radiograph table where it was found that after the removal of numerous blood clots and of pus due to the presence of a perinephritic phlegmon, the shell splinter localized by the radiograph near the ribs, had descended nearly down to the iliac fossa, and it was only by means of the radioscopic screen that it was discovered and removed.

Operative indications in the course of war wounds of the kidney are positive also when the renal hemorrhage, instead of stopping, becomes aggravated, when these hemorrhages occur, or finally

when the kidney presents a well-marked pyonephrosis.

I had occasion to examine, with Dr. Senn, chasseur S. R., 25 years of age, who had been wounded on June 17, 1915, in Metzeral, receiving a shell splinter in the left side. On admission to the hospital, he presented a rather serious condition, a weak and rapid pulse, facial pallor, and blanched integuments. A sharp pain was felt at the level of the twelfth left rib; there was an irregular wound, situated at the free end of the tenth rib, five centimeters in length by three centimeters in width, directed downward and inward, and from behind forward. The urine was very dark, and the patient said he had passed blood two hours after the injury. Examination of the abdomen afforded no information. Directly after his arrival, the patient was carried to the operating room. The wound was exposed and enlarged, in order to see if a shell splinter had been left behind. After an unsuccessful exploration, a stream of red blood suddenly appeared, the incision was extended in the direction of the anterior-inferior iliac spine, and the wounded left kidney was felt in the hand; the pedicle was compressed between the fingers, in order to make hemostasis, but after examining the renal parenchyma, it was decided to preserve the kidney, which was placed in a Marcille net. After good drainage was established the superficial parts were sutured. By July 20 the patient began to get up one hour daily, and his wound promptly healed under excellent conditions.

It was of interest to ascertain the functional capacity of this ruptured and sutured kidney. The necessary investigations were therefore carried out on August 18. In order to examine the condition of the ureter, catheterization of the left ureter was performed with a No. 6 catheter, which was introduced without difficulty to a length of 30 centimeters. The urine from each kidney was separately collected; the result of the analysis, as summarized in the subjoined table, shows that although the quantity of urine from the left kidney was slightly less, its quality was superior to that of the urine from the right kidney; plainly showing the importance of the preservation of this kidney for the patient.

	Right Kidney.	*Left Kidney.*
Quantity	61 c.c.	45 c.c.
Urea (per liter)	3.64 grams	6.40 grams
Chlorides (per liter)	10.53 grams	12 grams
Phosphates—The quantity of urine was insufficient for this estimation.		

In cases of secondary pyonephrosis the treatment is the same as in all pyonephroses, interference with the diseased kidney being permissible only when its fellow has been ascertained by segregation of the urines to be perfectly healthy and capable of taking sole charge of the urinary excretion.

Sometimes the lesions on the part of the kidney do not manifest themselves until a remote date. I have observed an illustrative case of unilateral suppurative nephritis following a gunshot wound at the base of the left lung. This interesting observation follows:

Unilateral Suppurative Nephritis, Abscess of the Prostate, Suppurative Vesiculitis, and Perivesiculitis Following Purulent Pleurisy Due to a Shell Splinter; Left Nephrectomy and Perincotomy.—Private S., aged 34 years, admitted October 8, 1917, to the Urological Service of the Dominique Larrey Hospital in Versailles, with the diagnosis of tuberculous cystitis. On September 25, 1915, he had been wounded at Souain by a shell splinter at the base of the left lung. After a temporary dressing at the first aid station, he was sent directly by hospital train to the temporary Hospital No. 5 in Montauban, where he was treated during several months for left-sided purulent pleurisy following his wound. On February 18, 1916, his condition had sufficiently improved for his being discharged on convalescent leave for three months. On his return to his post, as he continued to complain of pain in the left side, he was sent to the Hôtel Dieu of Laval, where a shell splinter was removed which had lodged at the base of the left lung. Notwithstanding this operation, the pains in the side still persisted, and on August 10, 1916, he was transferred by the Advisory Board to the auxiliary service.

On admission to the urological ward, he was still complaining of pains in the left thoracolumbar region, which for the past ten days had become associated with painful crises in the hypogastrium. Micturition was of normal frequency during the day, but during the night he urinated three or four times. A slight burning sensation was felt during micturition. He denied ever having had gonorrhea. The urethra admitted a No. 18 sound, and showed no trace of stricture. The prostate was normal, the right seminal vesicle could not be felt, but the left vesicle was thickened and painful. Lumboabdominal palpation showed an absolutely free right lumbar fossa, whereas on the left side a large and very hard mass was felt, fluctuating slightly, and passing up under the ribs. This mass was apparently referable to the kidney, surrounded by an area of perinephritis. The urine was turbid, and analysis showed the presence of pus, but the absence of tubercle bacilli.

On October 12 catheterization of the left ureter was performed, with a No. 7 catheter, which easily passed a distance of 30 cm. The capacity of the renal pelvis was 10 c.c. The analysis of the separate urines showed a normal right kidney, whereas the left kidney showed an insufficiency and contained pus.

On October 19 the patient was suddenly attacked by complete urinary retention, the nature of which was recognized by the rectal touch, in the form of a large resisting and very painful prostate. The patient was now treated with regular catheterizations and warm irrigations. On the 22d the prostate was felt yielding under the finger, on rectal examination; a flow of pus appeared at the meatus, the prostatic abscess having opened into the posterior urethra.

On December 23, as the temperature remained high, the patient was again examined. The prostate was found to have resumed its normal dimensions, but a large supraprostatic mass was felt, especially marked on the left side. The retrorectal region was infiltrated and edematous. On the next day, the physical signs persisting and the temperature remaining very high, an operation was decided on. The perineum was incised, and the finger passed up to the left of the bladder opened into a pocket, from which a large amount of pus was discharged. A drain at the level of the vesicula seminalis was inserted, and the operation was terminated, leaving the perineum temporarily open. Examination of the pus, collected in a sterile pipette, showed it to contain staphylococci. The temperature dropped slightly on December 24 and 25, but rose again on the 26th, and rectal examination showed that a new collection of pus had appeared at the site of the right vesicle. On the same day the patient was anesthetized, and this new collection was opened with the finger through the original perineal wound. The temperature still remained high for a few days and then dropped. The drains were removed December 31. On January 5 left-sided parotitis appeared, which subsided in a few days without suppuration. On January 16 all dressings were removed, the perineal wound having completely healed.

The patient's general condition remained bad, however, and his urine was always very turbid. The performance of another cystoscopy, showing a normal right ureteral orifice and a gaping left orifice with swollen margins, surrounded by a greatly inflamed and edematous area, confirmed the findings of the preceding urinary segregation. Ambard's constant was excellent, 0.067.

Radiography proving negative, the performance of nephrectomy was indicated. Under these conditions another intervention was decided on. Subcapsular nephrectomy, rendered necessary on account of the severe perinephritis surrounding the kidney, was performed on January 6. In the course of the operation, the kidney having been removed, a fistulous tract was discovered at the upper and posterior portion of the renal recess, at the level of the diaphragm, apparently

connecting the pleura with the renal recess, presumably representing the route followed by the infection in its propagation from the pleura to the kidney, first infecting the perirenal fat.

The excised kidney was large and nodular. On incision a suppurative nephritis was found, the renal pelvis and the calyces being intact; only miliary abscesses were seen in the cortical substance, and five or six purulent foci the size of a hazelnut. Bacteriological examination showed the pus to contain staphylococci.

The operative sequelæ were normal, and at the time of this report the patient is steadily improving, and on the highroad to recovery.

This observation is of twofold interest. In the first place, the genesis of the complications presented by the patient is somewhat unusual, and the assumption is apparently justified that the pulmonary lesion was the starting point from which originated the infection, first becoming propagated through the diaphragm to the perirenal space and then to the renal parenchyma. From here, by way of the ureters, it reached the prostate gland and the seminal vesicles. Bacteriological examination showed the same infectious agent, the staphylococcus, in the prostate-vesicular pus and in the renal pus.

Furthermore, this observation is noteworthy because of the rare occurrence of the lesions discovered in this patient—double perivesiculitis and suppurative nephritis without involvement of the calyces and the renal pelvis.

IV. WOUNDS OF THE TESTICLE.

Gunshot wounds of the testicles are not uncommon. As a rule, they are associated with other lesions of the urethra or the bony walls of the pelvis, and frequently they are accompanied by wounds of the thighs. In exceptional cases the injury is limited to the testicles alone.

The treatment to be adopted in this class of injuries must be *preeminently conservative*, unless the organ has been completely destroyed and its preservation is absolutely impossible.

The utmost care should always be exercised to preserve, if not the entire organ, at least the larger portion of the testicle. In other words, castration is to be performed as rarely as possible, and only as a last resort.

In view of the fact that wounds of the testicles occur in young men, well-marked disturbances of a general character are bound to follow. I have observed the case of a young soldier, 23 years old, who was wounded by a bullet which passed through both testicles, so that after the wound had healed only two small stumps were left, evidently without any testicular secretion. In consequence of this injury the patient sank into a state of extremely pronounced neurasthenia, with intellectual, moral, and physical depression of a very marked type. No internal treatment proved successful in restoring his previous state of health. He remained in a completely apathetic condition, unable to make any physical effort, stretched out on his bed throughout the day, and crying nearly all the time. Testicular medication, which had been administered, as well as injections of sodium cacodylate, and injections of physiological salt solution produced practically no effect.

Other cases have come under my observation in which only one testicle had been destroyed, and where the above described phenomena did not occur.

20 Rue de Grenelle.

Military Medical News.

Retaining of Men in the Medical Service.—Surgeon General Ireland, in a letter to the enlisted men of the Army Medical Department, made public on April 21, explains that it is not possible to discharge men in that department as rapidly as in other departments. He says that in spite of recruitments from organizations being demobilized it is necessary to retain in the service many enlisted men who have given long and faithful service and who can present good reasons for asking for release. He points out that all officers and men now in the service came in for the emergency, and that so far as the Medical Department is concerned the emergency is not yet over.

Little Insanity in the Army.—Statistics from the Medical Division of the War Risk Insurance show that only three out of every one thousand men called into the service were discharged for nervous or mental disorders, and many of these have since been restored to normal health. Of the 960 soldiers, sailors, and marines suffering from such ailments, who are undergoing treatment by the Government, 249 cases are of mild psychoneuroses, 126 are cases of epilepsy, 85 organic nervous diseases, and 501 are more serious nervous and mental disorders.

War Honors for Physicians.—At ceremonies held recently on Governors Island, Distinguished Service Medals were bestowed on Col. Grayson M. P. Murphy of the General Staff, and Col. James S. McKernon and Col. Charles H. Peck of New York.

Fourteen members of the American Red Cross Mission to Greece have been decorated by King Alexander for services rendered in relief work. Lieut.-Col. Edwin P. Capps of Chicago, head of the mission, has received the cross of the Royal Order of the Redeemer, which is the most important order of knighthood conferred in Greece.

The French Government has bestowed the Medaille de Reconnaissance upon Dr. M. Louise Hurrell of Rochester, N. Y., head of a unit of the American Women's Hospitals at Luzancy, France, and upon all other members of the unit, including nurses and chauffeurs. All the members of the unit have been made citizens of Luzancy.

Deaths in the Service.—Capt. Russell Cisney Parson, M. C., U. S. Army, of Ambridge, Pa., a graduate of Jefferson Medical College in 1914, who served with Evacuation Unit No. 13, and later as roentgenologist in the Toul sector, and in December was transferred to Hospital No. 91 at Le Banle, died there from epidemic lethargic encephalitis on March 1, aged 27 years.

Col. William Henry Comegys, U. S. Army (retired), a graduate of Miami Medical College, Cincinnati, in 1876, died in the Presbyterian Hospital, New York City, on March 31. He entered the army as acting assistant surgeon in 1879, and served in the Geronimo campaign. In 1881 he was appointed major and paymaster, serving in that department until 1911, when he was retired at his own request.

Lieut. William Latimer Hall, M. C., U. S. Army, of Freedom, Okla., a graduate of Emory University, Atlanta, Ga., on service with the Expeditionary Forces, died at Marseilles, France, from bronchopneumonia, on February 10, aged 29 years.

THE DIAGNOSIS OF ACIDOSIS.

ACIDOSIS has for years past been one of the fields of romance in Medicine. The term has lacked a satisfactory definition but has been used glibly in explanation of obscure conditions, often without a very clear conception of its real significance, and at times has been applied to conditions in which real acidosis can play no part. Moreover, unless the acidosis is marked, the diagnosis may present extreme difficulty. It is a great pleasure, therefore, to find such a clear and sanely critical review of the subject as that presented by Macleod (*Journal of Laboratory and Clinical Medicine*, 1919, iv, 315). He recounts the development in the use of the term, which was at first limited to the undoubted acidosis existing in cases of diabetic coma, then gradually extended to include all cases of acetonuria, and later included those conditions in which the acid production or retention involved entirely different types of acids. The difficulty in early diagnosis depended partly upon the lack of an adequate conception of the disease process, but chiefly upon imperfections in technique of the methods used.

The desideratum is an estimation of the total alkaline reserves of the body. The author points out the difference between hydrogen ion concentration and titrable acidity, explains the errors inherent in titration methods when applied to blood or body fluids, and shows the superiority of the colorimetric method, using phenolsulphonephthalein and a set of solutions of known hydrogen ion concentration. The total alkaline reserves of the body are the alkalinity of the plasma, the alkalies of the corpuscles, the protein of the blood, and finally the alkalies and proteins of the tissue cells. The "buffer action" of these alkalies depends in the plasma on the ratio H_2CO_3:$NaHCO_3$ and in the corpuscles and tissue cells also upon the ratio between the dibasic and monobasic phosphates. Now the percentage of CO_2 in the alveolar air must be a measure of the available $NaHCO_3$ in the blood, but in the methods now used "the alveolar CO_2 can serve as an accurate index of the acid base equilibrium of the blood only under certain controlled conditions," and these conditions are difficult of attainment. Direct examination of the blood as to its content of $NaHCO_3$ avoid certain errors, but still yields figures short of the total alkaline reserve of the body. The author prefers the method of Haldane, which employs whole blood, to that of Van Slyke, which uses only the plasma. Methods combining blood and alveolar air examination are scarcely more accurate or informative. Another method whose value is still to be determined is to estimate the output in the urine of acid salts, salts of ammonia, and free acid, for when foreign acid is added to the body a corresponding amount must be eliminated by the lungs and kidneys.

In the opinion of the author "the best test of acidosis at present available in routine clinical work" is to determine "how much alkali can be added to the organism without causing the urine to assume an alkaline reaction." Normally, this is very small, about 5 gm. $NaHCO_3$, but in acidosis may be as high as 100 gm. a day. The value of this test seems to be established by experimental work. It is easy of application under all conditions, and should be extensively employed in practice. Comprehension of the principles set forth, and an appreciation of the relative value of the methods discussed, will serve to eliminate much loose talk concerning acidosis. It is to be hoped that the paper will be widely and carefully read, for only in this way can its value be fully realized.

THE COST OF TUBERCULOSIS.

IT is slowly but surely being borne in upon the public in general that disease is economically injurious to a country, and that self-interest dictates that disease, and especially contagious disease, shall be got rid of as effectually as may be. The classical contagious diseases, of which syphilis and tuberculosis are the most destructive, are an economic incubus on a country. They paralyze to a great extent its industrial efforts and militate against prosperity and comfort. Therefore it is incumbent upon those in authority that, even from material motives, they endeavor to eradicate these diseases as far as is possible. The war has increased the prevalence of and emphasized the need for dealing with syphilis and tuberculosis. In order to obtain fairly satisfactory results each of these infections must be attacked at their roots. The problem of syphilis can perhaps be successfully solved only by preventive measures, and the problem of tuberculosis, in a lesser degree, can be properly dealt with only in a similar manner. The question of the remedial treatment of tuberculosis is not simply or chiefly one of medicine and hospital beds. Institutional treatment is all very well so far as it goes but it is a broken reed on which to lean when the aim of treatment is eradication. Of course, the difficulty to overcome in providing effectual preventive methods is to initiate treatment before the disease has gone too far. The working classes cannot afford to be ill and the disease has often passed beyond the early stages before the consumptive artisan or laborer is willing to give up work. Consequently in existing circumstances

preventive measures cannot be really effective, for the very obvious reason that they cannot be enforced.

As matters stand at the present time, as an editorial writer in *Reveille* for February, 1919, points out, the problem resolves itself into how to create conditions under which the consumptive can go on living and what is economically equally important can go on working. The first thing then to do with the tuberculous is to teach them to live as consumptives. This is the true function of the sanatorium, for work is essential to successful treatment. Prolonged unemployment means boredom, depression, and rapid moral and physical degeneration. It is almost impossible and very undesirable to procure work for the consumptive in the outside world, and medical authorities are fast coming to a full realization of this fact, and are in consequence advocating the adoption of the plan of industrial colonies for consumptives. Treatment and training must be linked together as was demonstrated in the clearest manner during the discussion on the tuberculous at the International Conference on Rehabilitation of Disabled Soldiers held recently in New York. At this meeting Captain Roddick Byers of Ste. Agathe des Monts, Quebec, and Dr. Bayard Crane of Rutland, Mass., dwelt insistently upon the benefits to be derived from occupational training for the tuberculous. Dr. Crane, in particular, urged strongly the establishment of industrial sanatoria and agricultural and industrial colonies for the tuberculous. Indeed the sentiment of all the speakers at the meeting appeared to be agreed upon this. In Great Britain a considerable amount of progress has been made in the carrying out of such views, and Dr. Varrier Jones has now in excellent working order at Papsworth, Cambridgeshire, England, an agricultural and industrial sanatorium and colony for consumptives. Owing to the diminished, ofttimes greatly diminished, earning capacity of consumptives, Drs. Jones and Bardswell, writing in the *Lancet* of August 3, 1918, insist upon the necessity for subsidizing consumptive labor. In the case of discharged soldiers this subsidy already exists in the shape of a pension, but they contend all labor of this kind should be subsidized. The argument for this procedure is as follows: On economic grounds the subsidizing of consumptive labor is justifiable, because otherwise the consumptive must inevitably cease to be a producer. The war has taught the value of man power as nothing else could. Thus it is patent that the worker who ceases to produce is a loss to the community. Ergo, the worker who dies slowly long after he has ceased to produce is a two-fold loss. The community loses not only what he might have produced but what he consumes after he has ceased to be a producer. It is cheaper in the long run to subsidize the consumptive worker even to the extent of 30 or 40 per cent. of his earnings if he can thereby be enabled to go on producing. Last, but not least, the consumptive is a constant source of danger to his fellow beings and because by spreading infection he is the means of incapacitating numerous other workers, he is a menace from the economic point of view. From whichever side the question is regarded, it is to the incalculable benefit of the community that the tuberculous shall be segregated in colonies where they may be partly self-supporting.

However, when all has been said that can be said concerning remedial schemes for the consumptive the essential facts of tuberculosis must not be minimized. The colony system, although necessary under present conditions, is only a makeshift, and by it tuberculosis will never be wiped out. It is a compromise plan devised to meet the situation until radical preventive means are carried into effect and we must not delude ourselves by the belief that it is anything else. So long as people are badly or inadequately fed, badly housed, and allowed or compelled to work under unsanitary conditions, just so long will tuberculosis flourish.

The main object of preventive medicine is to remedy present conditions of living in large cities. When this has been properly done, consumption will gradually vanish, but in the meantime steps must be taken to protect the public from infection and to render the consumptive as self-supporting and comfortable as circumstances permit. It is necessary to bring home to the laity the truth that to allow consumptives to dwell and work among a healthy community is bad for themselves and worse for others. When the public understand this there will be less indifference shown in the matter.

THE CONDITIONS WHICH PRECEDE BRIGHT'S DISEASE.

If one were to select from medical literature all of the alleged symptoms which antedate Bright's disease one would have as a result a fearful and wonderful procession of subjective and objective phenomena and doubtless would lose considerable respect for didactic medicine. The reason for this polysymptomatology is not far to seek. So long as the action of the kidneys is compensated the hundred and one symptoms which are present cannot be prodromes or early manifestations of insufficiency, but must be purely fortuitous happenings. On the other hand, when compensation is once affected one does not depend on subjective and rational evidence at all, but proceeds at once with laboratory tests. Realizing that students always want positive information, many teachers of the past have laid down statements concerning the initial manifestations of the disease which they only half believed and which could be found only in certain cases and were moreover vague at best. We are referring naturally to the chronic forms not attended by such obvious symptoms as edema and albuminuria. Honest clinicians have admitted that two weeks are often required for a diagnosis and some have placed reliance on slight enlargement of the heart shadow as the earliest laboratory

find, this of course being present in the still compensated case. Disturbed metabolism is also said to be discoverable during this period.

In *La Presse Médicale* for March 20 Nathan has discussed the problem of the conditions which precede Bright's disease. His angle is rather a novel one but his quoted cases are evidently past the compensated period. Nevertheless they throw light on the polysymptomatology of writers. Briefly, the slow approaches of retention of nitrogen form a strong predisposition to the revelation of weak points in the physical makeup. The alleged prenephritis dyspepsia is to be looked for in the predisposed subject. Some more advanced patients may be found to digest their food well by laboratory tests, while indigestion may be corrected by regimen as in normal subjects. If the patient have hyperchlorhydria, for example, he may respond to the proper treatment. Tuberculosis and bronchiectasis may mask nephritis as shown by blood tests. A case of the former is cited in which the blood nitrogen was 1.70. Apparently these patients have a high tension pulse. In many cases of labyrinth disease nephritis may be present. In a word, by lowering the general defense the personal equation of morbidity is revealed in late manifestations of heredity, to say nothing of infections. Nearly all cases of Bright's disease are masked by the individual or personal reaction.

Data about the Deafmute.

Interesting data about the deafmute are to be found in reference volumes, but the discrepancies are often notable and the absence of proper controls is at times significant. Institutional life for example may be responsible for some peculiarities ascribed to the disability. In the *Svenske Läkaresällskapets Handlingar* for December 31 the entire issue is devoted to an exhaustive study of deafmutism from the pen of Bergh. One Swedish province alone is concerned—Malmöhus, and the entire material, urban and rural, is analyzed, the total amounting to 383. There are about 8 deafmutes for each 10,000 inhabitants. Males outnumber females and as the proportion of female to male inhabitants is 106 to 100 this cannot be accidental. In regard to origin about 28 per cent. of cases were congenital and 63 per cent. acquired, while in 9 per cent. the origin could not be determined. Certain alleged uneugenic factors such as illegitimacy and discrepancy in parents' ages could be excluded as causes. Direct and indirect inheritance was of minor importance and abuse of alcohol in ascendants could be almost if not quite eliminated as a factor. Consanguineous marriages, like inheritance, played a small but assured rôle. In general, attempts to connect well known factors in the production of disease and malformation with deafmutism seem to have broken down. On the other hand certain data seemed quite meaningless, as a notable tendency to involve the left ear. The author analyzes his material from almost every possible angle, but in the end we arrive only at the conclusion that the deafmute is a defective *sui generis* and also a chance victim of infections in which there may of course be a predisposition. The number would diminish if we could banish smallpox, typhoid fever, cerebrospinal meningitis, and other infections and be authorized to treat promptly and continually all middle-ear disease in the young child.

Autoserotherapy of Influenza.

Aguirre, writing in *El Siglo Medico* for February 8, gives credit for this idea to Valero, who caused the formation of cantharides blisters near the foci of disease and then injected the serum subcutaneously. The technique of the operation goes back to Moduos, according to the author, who injects about 12 c.c. of the blister serum and repeats it soon if no good result is experienced. The presence of a large amount of albumin in the urine is a contraindication, according to Valero, but Aguirre believes that, on account of the great frequency of albuminuria, this may be going too far. If adopted, this restriction would automatically exclude most severe cases of grippe and the balance might be relied on to recover without such treatment. Aguirre tested the remedy on a series of cases in which albumin was absent and saw in from fourteen to thirty-six hours development of crisis or lysis. He is not prepared to say that the treatment offers advantages over other plans, but holds that its use is rational and that a remedy thus grounded should be given a trial.

News of the Week.

Ground Broken for Bronx Hospital.—Ground was broken for the new Bronx Hospital, at Fulton Avenue and 169th Street, on April 20. It was announced that the Bronx Hospital Society already owns the site and two buildings now standing on it. One of these buildings will house the hospital wards containing 100 beds, while the other will be used as a nurses' home and dispensary. The new building for which the ground was broken will contain the operating room, reception ward, and laboratories. A total of $60,000 has already been contributed toward the $100,000 needed for the erection of the new building.

Lenox Hill Hospital Needs Funds.—The report of the Lenox Hill Hospital, recently submitted by the board of trustees, makes an urgent appeal for funds and a drive for 10,000 members. An emergency fund of $100,000 is imperative in order that the hospital may meet the increased cost of maintenance, service, and equipment.

Improvements at Montfiore Home and Hospital.—At the annual meeting of the directors and others interested in this institution it was announced that the frame buildings at the country sanatorium for consumptives at Bedford Hills will be replaced with modern fireproof structures. It was also announced that Jacob H. Schiff had donated $150,000 for the erection of a cottage near the present institution on Gun Hill Road for patients who have reached a state of health where they do not require additional treatment but still remain helpless.

Philadelphia Leper Escapes—A leper found in a Syrian boarding house in Philadelphia disappeared on April 20, before the arrival of an ambulance

which was to convey him to the leprosarium of the Municipal Hospital. The police authorities feel satisfied that the leper fled to New York.

St. John's Guild Seeks Funds for Nurses' Home.—St. John's Guild, which for the past fifty-two years has been operating the Floating Hospital in New York harbor and the Seaside Hospital at New Dorp, Staten Island, has begun a campaign to raise $150,000 for a nurses' home at the Seaside Hospital. The records of the Guild show that the Floating Hospital has treated 1,680,000 patients, while at the Seaside Hospital 750,000 patients have been cared for.

Permanent Exhibition of Safety Appliances.—Park Commissioner Francis D. Gallatin has signed a lease giving the Safety Institute of America the right to occupy the Arsenal in Central Park, New York, for the purpose of a permanent exhibition of safety appliances for the prevention of accidents to working people. The building will be restored to its original condition at a cost of about $125,000. The Institute plans to expand its work by visualizing the best type of playgrounds and recreational centers through models. In announcing these plans, attention is called to the fact that there are some twenty safety institutes and museums of safety in Europe, while this is the only one of any size in the United States.

Dr. Foster Kennedy, late Major Royal Army Medical Corps, British Expeditionary Force, has returned to this country and resumed his practice at 20 West Fiftieth Street, New York City.

Dr. James T. Pilcher, having been mustered out of the United States Army, will resume his private practice at 145 Gates Avenue, Brooklyn.

Dr. Daniel N. Eisendrath having been released from military service, has resumed his practice at 4840 Woodlawn Avenue, Chicago.

Dr. W. N. Hunt of Burlington, Wash., has been appointed county physician of Skagit County.

Gives Library to Medical Society.—Dr. Russell M. Cunningham, formerly Lieutenant Governor of Alabama, has donated his medical library, which was one of the best private medical libraries in the South, to the Jefferson County Medical Society.

New York Neurological Society.—A stated meeting of this society will be held at the Academy of Medicine on Tuesday evening, May 6, at 8.30 o'clock. Papers will be read on "Encephalitis Lethargica," by Drs. Bernard Sachs and Isador Abrahamson, and on "Gunshot Wounds of the Head," by Major K. Winfield Ney, M. C., U. S. A.

Federal Positions Open to Physicians.—The United States Civil Service Commission announces the following examinations to be held June 3, 1919, in various cities in the United States and in the Canal Zone, to fill the following positions: *Assistant epidemiologist*, male, to fill vacancies in the Public Health Service, at a salary ranging from $2,000 to $2,500 a year. Applicants will be rated on general education and medical training, laboratory experience, experience in epidemiological work, and publications or theses. *Consulting physiologist*, male, to fill a vacancy in the Bureau of Mines, Washington, D. C., at $10 per day when employed. The duties of the employee will be to study the physiology of gas poisoning with special reference to gases in mines and manufactures associated with mining. A degree of M.D. or Ph.D. from an institution of recognized standing, and at least two years' experience in the physiology of respiration and poisonous gases are prerequisites for consideration for this position. *Assistant to medical director*, male, to fill a vacancy in the United States Employees Compensation Commission, at a salary of $2,000 a year. Applicants must be graduates in medicine and have had at least one year's experience in Federal, State, or municipal employ. Applicants desiring to take these examinations should apply for Form 2118, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., where further information may be obtained.

The Relation of Venereal Disease to Crime.—Dr. James A. Hamilton, Commissioner of Correction of New York City, has issued a statement commenting upon the relation of venereal disease to crime, and raising several questions as to methods of dealing with the criminals infected with these diseases. He states that a great majority of male prisoners give a history of venereal infection at some time or other, and among female prisoners practically every case gives a venereal history or shows a positive Wassermann. The question raised is whether a prisoner shall be liberated when he shows a 4 plus Wassermann, or whether it is safe to allow such prisoners to mingle in the workshop or to sleep with healthy ones. In discussing the first question, Dr. Hamilton expresses the opinion that it would be abviously unjust to keep a prisoner in jail until the Wassermann became negative; but on the other hand, if salvarsan is administered the Wassermann may become negative for a few months and then become positive again. He suggests that these individuals be paroled, and compelled to take treatment, and report at stated intervals, bringing proof that they are being treated.

National Association for the Study of Epilepsy.—The eighteenth annual meeting of this organization will be held at the Craig Colony for Epileptics, Sonyea, N. Y., June 6-7, 1919, under the presidency of Dr. William T. Shanahan. In addition to an interesting scientific program there will be a reorganization of the society to meet the demands of the post-bellum period, and plans will be discussed for a union of the investigators of the epilepsies in allied and neutral countries with those of America.

Rabies in England.—An outbreak of rabies in England, the first in twenty-one years, is reported to have reached almost epidemic proportions, and has caused the authorities to issue a muzzling order affecting 700,000 dogs, which went into effect on April 24. England has for many years enjoyed practical immunity from hydrophobia, and it is assumed that preoccupation with the war has led to carelessness in enforcing the regulations which have hitherto enabled them to control the disease so successfully.

Influenza Sweeps India and the Belgian Congo.—According to a report to the Associated Press, almost 5,000,000 persons have died in British India from influenza and a million others are believed to have perished in the native states from the same cause. The mortality rate from the disease is said to have been 20.6 deaths per 1,000. The figures show

that within a period of a few months the influenza epidemic claimed half as many victims as did the plague in twenty years. A great loss of life among the natives of the Belgian Congo is reported in despatches received from Brussels. Estimates place the number of deaths at 500,000.

The Allied Blockade Decreased German Births.—The Imperial Health Ministry of Germany has issued a memorandum on the results of the Allied blockade, which states that from 1915 to 1918, as a result of undernourishment, 763,000 persons died in Germany, and an additional 150,000 died of influenza because of lowered power of resistance. The fall in the number of births during the war is said to exceed 4,000,000 for the empire and more than 2,500,000 for Prussia. The memorandum calculates the financial damage done by the blockade at $14,075,000,000, in which are included such curious items as unborn children, and the loss of wages due to decreased earning power.

Smith Memorial Maternity Hospital.—At the graduation exercises of the Training School for Nurses of the Lankenau Hospital, Philadelphia, held April 9, announcement was made that a sum in excess of $125,000 had been donated by Mr. Charles Smith for the construction of a new maternity hospital to replace the present building, also the gift of the same donor.

Charitable Bequests.—By the will of the late Ellen Craig of Philadelphia the sum of $5,000 is bequeathed to the Episcopal Hospital.

By the will of the late Miriam H. Wolf of Philadelphia the sum of $5,000 is bequeathed to the Jewish Hospital Association of Philadelphia for the Home for the Aged, and the residuary estate to the Hospital of the University of Pennsylvania for the establishment, maintenance and equipment of a ward for incurables as a memorial to her husband, the late Abram Wolf.

Obituary Notes.—Dr. BENJAMIN G. ALLEN, a graduate of Beaumont Hospital Medical College, St. Louis, Mo., in 1888, died suddenly of heart disease at his home in Chattonooga, Ga., on April 11, aged 51 years.

Dr. CALVIN SLOANE MAY, a graduate of the Medical Department of Yale University, in 1873, died suddenly at his home in New York City on April 26, aged 71 years. He was a member of the American Medical Association and the New York Academy of Medicine, and was at one time acting superintendent of the Connecticut Hospital for the Insane.

Dr. FLOYD S. CREGO, a graduate of the Cincinnati Medical College in 1879, died suddenly at his home in Buffalo, N. Y., of angina pectoris, on April 23. He was a member of the American Medical Association and the Buffalo Academy of Medicine. He was consulting neurologist to the County, German, Mercy, Emergency, and Children's Hospitals. For some years he occupied the chair of nervous diseases at the Niagara University.

Dr. GREENVILLE M. WEEKS, surgeon in the United States Army and Navy during the Civil War, and the last survivor of the *Monitor*, died at the Soldiers' Home in Kearny, N. J., on April 26, aged 82 years. He was a graduate of New York University Medical College, in 1861, and formerly resided in Newark, N. J.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, April 2, 1919

Causation and Prevention of Industrial Accidents.—The publications of the Health of Munition Workers Committee, as well as various public pronouncements made before the Royal Society of Medicine and other scientific bodies, have let a flood of light in upon the causation of industrial accidents, and the circumstances which promote or decrease their frequency. Dr. H. H. Vernon, who is official investigator to the Industrial Fatigue Board, has recently stated that every year in England alone a thousand workers are killed in industrial accidents, this figure being exclusive of accidents to miners—while over 100,000 suffer injuries which incapacitate them for a longer period than a week, and as many as two million suffer minor injuries. At a fuse factory employing 9,000 workers, the accidents were tabulated for a quarter of the year 1915, and for the whole of the years 1916 and 1917, the varying factor in the periods being that during 1915 the operatives were working 75 hours a week, whereas in 1916 the working hours only amounted to 64½ per week, and in 1917 to 54½ per week. The first thing noticed was that of three-fourths of the accidents, namely, the cut hands, the number was at a minimum at the first hour of the morning's spell of work, increasing steadily throughout the morning. This, however, was only when the operatives were working on the 12-hour day, or 75 hours a week. On the 10-hour day there was no such rapid increase of cuts during the morning's spell. Among women this difference was also marked, but with this variation, that, even when working 10 hours per diem, the morning increase of cuts occurred. In the afternoon spells of work in both sexes, the accidents were three and a half times more numerous in the 12-hour day than in the 10-hour day; and the influence of fatigue was further proved by the fact that the women were treated for faintness more than twice as often in the 12-hour day as in the 10-hour day.

Other factors in the causation of industrial accidents which have been debated are the speed of production, the temperature and illumination of the factories, and among operatives, the hours of rest and the habits of temperance. Both in the morning and in the afternoon spells of work at the munitions factories, the output was speeded up toward the end of the shift, presumably in order to attain to some guaranteed figure of production. The number of accidents rose concurrently and was certainly influenced by the pace as much as by the concomitant fatigue. The temperature of the factories played an important part. Accidents both to men and women were far more numerous in inefficiently warmed factories, and somewhat more numerous when the temperature of the building rose above 70°F. It would seem that accidents in factories are at a minimum when the temperature of the workrooms ranges between 60° and 70°F. There is no need to insist

on defective artificial illumination as a cause of industrial accidents, but here cuts of the hand appear not so much to be in question as actual injury of the face, and possibly to the eye, owing to the operative getting too close to his or her work.

While much attention has been paid to the conditions of labor as influencing the occurrence of accidents, the individual habits of the operatives are certainly not without their share in the causation. Through 1916 and 1917, when the average sobriety was greatly increased by the restrictions on the sale of alcoholic liquids, both among men and women there appeared a steady diminution in the excess of accidents usually incurred during the first spell of night work, *i.e.* the work immediately following upon the most likely time for alcoholic refreshment. Accidents, moreover, were always found to be at a maximum on Monday, following on the opportunities given by the week-ends for alcoholic excess. With regard to the time at which rest is taken, the incidence of night shift accidents appears, according to Dr. Vernon, to be the reverse of that observed in the day shift; that is to say, the accidents are at a maximum when the workers first come on. The suggested reason is that the workers do not come on immediately after a night's rest, but subsequent to three or four hours social contact, housework, shopping, amusements, and so on.

The war has certainly provided social workers with an enormous amount to think about in the future. In every direction masses of information and statistics, based on irreproachable evidence, are finding their way to public notice. The risk of course is that a feeling may arise that there is so much to be done that it is hardly worth while to begin to do it yet. The hope of the medical profession of course is that voluntary workers will keep alive in the mind of the Government the necessity for manysided and immediate reforms.

Death of Sir James Mackenzie Davidson.—The death is announced, as I write, of Sir James Mackenzie Davidson, the pioneer of applied radiology in medicine, as far as England is concerned. Born in Buenos Ayres of Scottish parents, educated in Edinburgh, and practising in Aberdeen and London, he was a fine example of the cosmopolitan medical man. His first bent was toward ophthalmology, and at Aberdeen he was assistant to the professor of that subject as well as university lecturer, and ophthalmic surgeon to the Royal Infirmary. But in 1897, after fifteen years of first class ophthalmic work, he came to London and devoted his attention to the application of the newly discovered *x*-rays to surgery. He promptly invented the precise method of localization by means of *x*-rays for foreign bodies in the orbit, which is still in everyday clerical use, and from his work there have arisen many developments for the localization of bullets which have proved of infinite service during the war. He was at the time of his death consulting radiologist to many military hospitals as well as to Charing Cross Hospital in connection with the Roentgen Ray Department, and president of the Roentgen Society. At the International Medical Congress, which met in London in 1913, he was president of the radiology section. Sir James Mackenzie Davidson was 63 years of age.

The Position of Ireland under the Ministry of Health Bill.—The proposed exclusion of Ireland from the most important piece of domestic legislation which has been contemplated in this country for at least 50 years has led and is likely to lead to considerable parliamentary debate. This exclusion of Ireland from the operation of the ministry of health bill appeared very important, but it was of course not intended to be permanent or designed to show that there was any less desire to promote the public health of Ireland than that of England, Scotland or Wales; the sensible idea on the part of the Parliamentary draftsmen was to get as much constructive legislation as possible into one bill. The local conditions in Ireland are such that clauses necessary for Ireland would have no meaning in other parts of the Kingdom, while clauses necessary for other parts of the Kingdom might not be required in Ireland. The Attorney General for Ireland, Mr. A. W. Samuels, has now asked Dr. Addison, as Minister in charge of the Ministry of Health Bill, to insert a clause in the bill constituting an Irish Public Health Council to give advice and assistance to the Chief Secretary for Ireland in taking steps to secure measures conducive to the health of the Irish people. The clause proposes to constitute the Irish Public Health Council as follows: three officials from the Local Government Board for Ireland, one or more from the Irish Insurance Commissioners, the Registrar General of Irish statistics, and three registered medical practitioners, one of whom shall be a woman and one a diplomat in sanitary science. Certainly the body proposed is not a democratic one; there is no provision for any professional voice in the matter. The registered medical practitioners, it is suggested, shall be nominated by the Chief Secretary for Ireland, and the other five or six officers are already in State employ. There is no room for general medical opinion in the Attorney General's proposals. Nor does it seem certain whether a body so constituted would be competent to take the steps to carry out and coordinate measures for the prevention and cure of disease, the treatment of physical and mental defects, the training of persons for health service, and so on. But these are matters that will be gone into by the Standing Committee of the House of Commons who will report upon the Ministry of Health Bill at an early date. It must be hoped that drafting difficulties will be surmounted, and that reclaim will obtain what all Irish medical practitioners want.

There are strong reasons why a Ministry of Health Bill should be formulated for Ireland. To begin with, the County Councils in Ireland have not the sanitary authority that they possess in England; secondly, public health legislation in Ireland is permissive not mandatory, and consequently is largely ignored. Notification of tuberculosis for example, being permissive in Ireland is carried out in only 69 out of 311 sanitary districts. Again, when in 1917 measures for combating venereal diseases were extended to Ireland, the consent of the Irish County Council

was required before the Local Government Board for Ireland could make provision in accordance with the Public Health Act. Few of these County Councils have consented, some have definitely refused, and others must be presumed to be making up their minds—they have not answered and, for practical purposes, may be considered as having refused to combat venereal disease in the country. Thirdly, there is no proper medical sanitary service in Ireland. There are hardly any wholetime and independent medical officers of health, and the work of such officers is discharged by medical men who are also in general practice and are dependent for their positions on the votes of the minor local government officials, District Councils, members of Boards of Guardians and so on, in whose hands the appointments, such as they are, are vested. It is the business of these people to keep down expenses, and a reforming medical officer of health would very soon be told to leave the district lest his zeal should eat up the public revenue. There is a good deal of hospital accommodation in Ireland, probably more buildings than are required, but a large proportion of the institutions are unfitted for modern scientific work. Great economy would be effected and greater efficiency by scrapping such places. There is in Ireland no provision for the medical inspection of children. There is a poor law medical service which is over-worked and terribly under-paid; and there is a general presence of illness and of liability to illness which requires strong preventive measures. Such are in brief the arguments for applying the Ministry of Health Bill to Ireland. It will be a thousand pities if the amendment to the bill concerning Ireland falls short of practical effectiveness.

OUR LETTER FROM PARIS

(From Our Own Correspondent.)

PARIS, March 20, 1919

A Memorial Hospital in Paris.—Colonel House has just communicated to M. André Tardieu, High Commissioner for Franco-American War Affairs, the details of the plan for a Paris hospital, to be maintained by American donations in commemoration of the soldiers of the United States who died in France during the war. The plan was originally submitted by Dr. Kenneth Taylor, who during the past four years has specially devoted himself to the question of hospitalization in France and who is now director of the American hospital of the rue Puccini. As to the scope of the proposed memorial institution, it is understood that its primary object will be to give French and Allied indigent invalids the medical care which their condition may necessitate. A further object will be to create closer relations between the French and American medical corps by enabling American students to acquire a thorough knowledge of French methods and by demonstrating American methods in clinics open for French students. Finally the hospital will be a center for French and American medical information and also a training school for French and American nurses.

The Hospitalization of American Soldiers in France.—When the American troops began to arrive in France in force measures were taken to ensure the proper hospitalization of sick and wounded men. A number of buildings were provided by the French authorities, while the American army authorities put up base hospitals and camp hospitals at suitable points. It was arranged that provision should be made in France for hospital accommodation for ten per cent. of the effectives, if required. On July 13 last, a request was made to the French Government that 45,000 beds should be placed at the disposal of General Pershing. In military hospital barracks, hotels and other buildings 50,000 were prepared and arrangements were made for 200,000 to be ready by January 1, 1919. Owing to the conclusion of the armistice it was not necessary to utilize more than 63,000 of these beds. It is considered, in view of these figures, that the difficult problem of hospitalizing American soldiers in France was dealt with satisfactorily from the outset.

The Jewish Welfare Board, which has rendered a broad service to the army and navy of the United States since America entered the war and which has maintained a large personnel in France for the last nine months, has embarked on an extensive reconstruction program through which the organization hopes to be of great aid to the demobilized soldier and sailor in his effort to resume his prewar status. For the purpose of carrying out this plan Colonel Harry Cutler, of New York, chairman of the executive committee of the Jewish Welfare Board, has come to Paris as head of the staff of workers in France, which will be largely increased. Through its field representatives with the army in Germany and at most of the large army centers in France, the Jewish Welfare Board is prepared to concentrate its resources on provision for the comfort and happiness of the soldier. Additional canteens are to be opened, many men and women field workers will be sent to the various camps and ports of embarkation, and assistance will be given the men on their journey homeward. Special attention is being given by the Board to the large ports of embarkation such as Brest, Bordeaux, and Marseilles. Large staffs are being maintained at these places to give every assistance to the troops as they leave for home. Through the Board's work in the United States and France every member of the Jewish faith in the service has been reached and helped; the aim of the Board is to continue that assistance until the men are again established in civil life. To make this possible, the Jewish Welfare Board is cooperating with the United States Employment Service and a Central Committee composed of representatives of all welfare bodies. Throughout the war, special attention also has been given to the hospitals. The Board has maintained workers in most of the large hospitals in France, and the United States. They wrote letters for the men, provided delicacies, and furnished entertainment; this in cooperation with the American Red Cross.

The Hospital Founded by the Women's Apparel Unit of the American Women's Overseas Hospitals at Labouheque, Landes, for refugees and civilians

during the war has been handed over with 100 beds, the need for its work being finished, to the French War Ministry for the use of convalescent soldiers. The director, Dr. Marie N. Formad, and her associate, Dr. Mabel Seagrave, who have left for America, have been awarded the Medaille d'Honneur pour les Belles Actions by the French Government.

Vital Statistics of Coblenz.—In noting figures in the rationing of the population of Coblenz, the following figures on the death and birth rate taken from the records are interesting to consider: On a basis of 10,000 population (the population of Coblenz is 57,000), the death rate in 1914 was 204, while in 1917 it was 291. The death rate from tuberculosis on the same basis was approximately 14 per cent. in 1914 and 29 per cent. in 1917. The birth rate in 1914 was 221 and 156 in 1917—a slight increase over 1916. The death rate for children under five years of age on the basis of 1,000 population was 392 in 1914 and 681 in 1917.

Closing of the American Field Service.—Four years of work with the French armies will be concluded with the closing of the American Field Service headquarters at 21 rue Raynouard on April 15. On this date the building occupied by the headquarters and the club for the old members of the service will be closed and transferred to New York, where a new American Field Service club is to be opened. The American Field Service was the first volunteer help to France in the early days of the war, and during four years has rendered valuable service to the French. When the United States entered the war it turned over its ambulance and ammunition transport service to the American army. The American Field Service, or the American Ambulance, as it was formerly called, had its start in September, 1914, when the battle line surged close to Paris. A dozen automobiles were hastily extemporized into ambulances, and, driven by American volunteers, ran back and forth night and day between the western end of the Marne valley and Paris.

During the following autumn and winter more ambulances were given and more Americans volunteered to drive them. Later they were placed in service between front-line dressing stations and the evacuation hospitals. From this time the American Field Service grew until ten ambulance sections had been organized, and these saw service on every part of the front from the North Sea to the Balkans. It was through the efforts of Colonel A. Piatt Andrew, inspector general of the service, that the Ambulance Service was given a trial at the front and its reputation was established.

In the spring of 1917 the French asked the Field Service to supply personnel for transport sections to carry ammunition, troops and shells. This request was complied with, and at the end of the summer of 1917 sixteen transport sections were serving with the French on the Chemin des Dames. At the same time thirty-two ambulance sections were serving on various sectors of the front.

The American Field Service turned over both services to the American army in the autumn of 1917, and they became the United States Army Ambulance Service and the Mallet Reserve. The U. S. A. A. S. was later increased by personnel from the ambulance school at Allentown, Pa., and the Mallet Reserve was increased by the 407th, 408th, and 409th trains which were sent over in February and March of 1918.

Of the old volunteer members five have been awarded the Medaille Militaire by the French Government. Two hundred and fifty ambulance drivers have been awarded the Croix de Guerre. The Mallet Reserve has been cited in French army orders and the French Government has more than fifty times cited the Ambulance Sections for distinguished service. The success of the service is in no small measure due to the efforts of Mr. Henry D. Sleeper, who as director of the American Field Service and representative in America, formed committees to rouse interest in the service both in regard to finance and recruiting. In recognition of his services the French Government awarded him the ribbon of the Legion of Honor.

146, Avenue des Champs Elysées

HEALTH INSURANCE AND THE STATE MEDICAL SOCIETY.

AN OPEN LETTER TO THE MEMBERS OF THE HOUSE OF DELEGATES, MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Gentlemen:—Two years ago your members who were to elect a president of the Medical Society of the State of New York were petitioned on behalf of two candidates for this office, Dr. Alexander Lambert and Dr. James F. Rooney. Dr. Lambert was advocated as the "logical candidate" on account of his labors for the State Society, Dr. Rooney for his services as chairman of its legislative committee. In discussing these nominations it was said at the time that the profession had fallen upon evil days through drug legislation, compulsory health insurance promotions, and the iniquitous provisions of the medical fee bill of the workman's compensation law.

Dr. Lambert was elected president of your society, a step which secured his subsequent elevation to the presidency of the American Medical Association. Except for a brief interval, Dr. Rooney has continued to serve as chairman of your legislative committee. He also has been honored meanwhile by your body in his elevation to the vice-presidency of the State Society. While both these candidates have grown in honors and distinction what has been the status of the great body of the profession which you represent during this period? It has been steadily going from bad to worse. For the fourth time we have just emerged from a life-and-death struggle against a "Health Insurance" law which, if enacted, would have meant the extinction of medicine as an independent profession and the sinking of the private practitioner in this State into the position of a health officer of the State, under the jurisdiction of the State Industrial Commission.

Against the united opposition of the medical profession of this State to this measure we have had arrayed in favor of it the Democratic Party, the Governor of the State, the Republican Senate, the

State Federation of Labor, and the well-nigh omnipotent influence that comes from no one knows where, but which is determined to force the "Socialization of Medicine" upon the American people. Added to these was the president-elect of the American Medical Association and your late president, Dr. Alexander Lambert, the only physician in private practice who appeared among the proponents of compulsory health insurance at the legislative hearing at Albany, where he offered in evidence the findings of the committee on health and public instruction of the American Medical Association, of which he is the chairman.

A less courageous, but far more dangerous, opposition than that enumerated exists within our own ranks, which, while opposing compulsory health insurance laws, is in favor of the principles of compulsory health insurance, and more or less covertly counselling with its advocates.

The logical candidate for president of the Medical Society of the State of New York to-day is one who has neither sympathy, support, nor traffic with the aiders, abettors, or advocates of drug laws, compulsory health insurance, or the medical provisions of the fee bill of the workman's compensation law. Your nominee should be one who can advocate your cause without mental reservation, without fear, and without self-interest. Let the Medical Society of the great State of New York go on record as the defender of the inalienable right of its humblest member to practise medicine as a free and independent calling, in the way our predecessors practised it, and not as that of a political employee of the State, depending for favor upon politics and politicians.

JOHN P. DAVIN, M.D.,

Member of the Medical Society of the County of New York.

3. Use of Human Serum in Treatment of Influenza Bronchopneumonia.—E. W. Gould reports that since last September 842 cases of pneumonia have been treated under the jurisdiction of the U. S. Naval Hospital at New York. Of these cases, 320 were treated at the hospital, the others being sent to civilian hospitals. Only such cases as were already diagnosed as pneumonia were treated at the Naval Hospital, and among these 320 cases the mortality rate was 26.16 per cent. Gould draws attention to the variation in the mortality rate in pneumonia; during February, March, and April of last year it was a little over 21 per cent.; in May and June they had a series of eighty-five cases without a death, though practically the same treatment was given; at the beginning of the influenza epidemic in September, the rate was 50 per cent., and toward the end of the epidemic it dropped to about 10 per cent. In September the method of treatment proposed by Lieutenant Redden was tried. Thirty cases of influenza pneumonia were treated with human serum from convalescing patients, with a loss of only two. Although the death rate had already begun to fall, the author feels that the immediate and remarkable response in many cases could be attributed only to some specific antibody injected. Cases were met with which presented the characteristic early depression and cyanosis of influenza pneumonia with a leucopenia, but gave no response to repeated injections of human serum. The infective agent in many of these cases was later shown to be the Streptococcus hemolyticus. Including all cases which received even a single dose of human serum, the mortality rate during the last two months has been very unsatisfactory, namely 26 per cent. Excellent results have been obtained with the use of serum from some donors who had shown a moderate leucocytosis before their last attack, and Gould is of the opinion that in such cases it may be a question of using a serum from a mixed infection including the influenza bacillus and the Streptococcus hemolyticus and that this serum may contain valuable immune bodies for homologous strains. The pooling method has not been employed and an endeavor has been made to match the recipients and donors as far as possible, and while remarkable results have been obtained from the use of certain donors, others have shown no apparent results. It has not been possible to confirm the contention of Lieutenant Redden that the amount of lung involvement in the donor determines the value of the serum, although this may be of some importance. The results obtained indicate that human serum from convalescent pneumonias undoubtedly contains valuable antibodies and that its use in cases infected with homologous strains will give satisfactory results, but it is believed that with our present limited ability definitely to isolate the infecting organism of the donor and the recipient, the method cannot yet be placed on a practical basis where definite results can be reasonably expected. The difficulty of procuring suitable donors must also be considered. No bad effects have resulted from the withdrawal of 400 c.c. to 500 c.c. of blood from donors at each of two sittings at intervals of two or three days. Only such patients as were convalescent and had had normal temperature for several days were used as donors, but it was not found necessary to wait until the lung had fully resolved. The bleeding usually resulted in an excellent appetite; no untoward effects were seen. Gould points out that cases of pneumonia vary greatly in their clinical aspects and apparently are due to various organisms, and that it would seem that only a small number of cases now appearing can be attributed to the same inciting factor as existed last fall.

3. Duodenectomy: A New Method.—James J. Moorhead and Herbert E. Landes describe a new method of duodenectomy, which after repeated attempts extending over a period of several years they have succeeded in devising. Their experiments were first undertaken to ascertain whether the duodenum is one of the so-called vital organs, and if so, the nature of its vital function. The method described permits of the complete removal of the duodenum in consecutive operations: (a) pylorectomy, closure of the duodenal end, and gastrojejunostomy; (b) transplantation of the common bile duct and the major pancreatic duct into

the jejunum; (c) removal of the duodenum. Since dogs thus operated on will live in a normal state of health, the authors conclude that the duodenum is not essential to life. They point out that the method possesses the following advantages: The gastro-enterostomy performed in the first stage is superior to the usual operations because the juncture is made at the true physiologic location, the pylorus, and this region is undisturbed in the subsequent steps. The biliary and pancreatic secretions are preserved. The jejunum is made to serve as a substitute for the duodenum in receiving the digestive juices. They state that in a review of the literature they were unable to find a single instance in which both the common bile duct and the pancreatic duct had been successfully transplanted into the jejunum at one time; that cholecystenterostomy in the dog is frequently fatal, and that cholecystogastrostomy disregards well established principles of digestion. In their opinion the usual technique of intestinal resection cannot be applied to the duct bearing portions of the duodenum, whereas the final stage of the operation described disturbs neither the pancreas nor the functioning alimentary tract, thus reducing to a minimum the after-effects of a severe operation.

1. A Lecture on the Lessons of the War and on Some New Prospects in the Field of Therapeutic Immunization.—Sir Almroth Wright points out that the war has taught two great lessons in immunization: that if the surgeon provides the requisite conditions—by excising all devitalized and heavily infected tissues and bringing the walls of the wound together—the protective mechanism of the body can, without any antiseptics, deal successfully with any kind of infection; and that the natural powers of resistance of the human body can be powerfully reinforced by inoculation, as has been proved by the success obtained with typhoid inoculation. He reminds us that long after the principle of prophylactic inoculation had been established, the inoculation of microbes into the already infected system was accepted as illogical. Pasteur was the first to teach that a vaccine might legitimately come into application in the incubation period. This was the beginning of therapeutic immunization. It was then thought that immunization took ten days to establish itself. When the author showed that bactericidal substances were rapidly elaborated, the question arose as to the particular stage of generalized infections at which one was to regard the body as overmastered by the bacterial poison and incapable of further immunizing response, whether localized infections should be envisaged as generalized infections indefinitely arrested in their incubation stage, and whether they might not be brought within the sphere of inoculation. Further consideration showed that the body should not be considered as a single and undivided unit; that in generalized infection it is presumably the entire body which is incited to respond, whereas in localized infections there is — with some reserves — only localized response. Therapeutic immunization, therefore, is theoretically permissible as long as there remains any part of the body which is not making its maximum immunizing response, and the program of therapeutic inoculation would accordingly consist of exploiting in the interests of the infected regions of the body the immunizing responses of the regions which are uninfected. The successes and failures of vaccine therapy have brought out the following points: Vaccine therapy is generally unsuccessful where the infection, as in phthisis, is producing constitutional disturbance and recurring pyrexia; also where we have to deal with unopened abscesses, or sloughing wounds with corrupt discharges; or in long-standing infections where vaccine therapy is much less successful than in recent infections. To combat bacterial infection, the organism must have defensive powers—*phylactic power*. The leucocytes and the bacteriotropic substances in the blood fluids may be called phylactic agents. There must also be provision for the transport of these phylactic agents to the site of infection, and this the author has named *kataphylaxis;* any condition which interferes with that transport is an *anti-kataphylactic influence*. In addition to these normal defenses of the body, which Wright has termed *phylaxis* and *kataphylaxis*, there are also resources in reserve by which the phylactic powers of the blood fluids can be increased—*epi-phylactic reinforcement* or *epi-phylactic response*, which manifests itself in connection with infections which give rise to constitutional disturbance. The author here points out that it would be more conformable to the terminology advocated to speak of the *apo-phylactic* rather than the *negative* phase when referring to the diminished blood resistance which follows directly upon the inoculation of a large dose of anti-typhoid vaccine. He also proposes that instead of the terms "regions of diminished bacteriotropic pressure," "non-bacteriotropic niduses" and "non-bacteriotropic envelopes," which he used in connection with typhoid and Malta fevers twenty years ago, *ec-phylaxis*, *ec-phylactic region*, and *ec-phylactic envelope* be used. Every living bacterial colony must become the center of an *ec-phylactic* sphere by (a) radiating out toxins which will (when of sufficient strength) repel leucocytes; (b) absorbing bacteriotropic substances from the blood fluids; (c) abstracting anti-tryptic power from the blood fluids and so converting these into a congenial culture medium. A fundamental contrast exists between the conditions in preventive and therapeutic inoculation. In the former resistance and phylactic power are normal; to these are added the reinforcement contributed by the epi-phylactic response, and the maintenance of normal and possibly improved kata-phylactic arrangements. In therapeutic inoculation it is important to realize that should epi-phylactic response of kata-phylactic reaction make default, therapeutic inoculation is almost bound to miscarry; in cases of continuous or frequently recurring pyrexia, the epi-phylactic, and in cases of unopened abscess the kata-phylactic reaction makes default. In cases in which there is interference with epi-phylactic response, the best procedure is to incise and evacuate the contents of the focus of infection, and where this is inapplicable recourse must be had to immobilization, local in the case of a limited local infection and "absolute rest" in a more extensive infection, such as the pyrexia of phthisis. Almost all failures in the vaccine treatment of bacterial disease, however, are due to frustrated kata-phylaxis, and in these cases three different types of kata-phylactic measures may be resorted to: (1) The contents of the ec-phylactic focus may be evacuated. Then by the emigration of fresh leucocytes and the transudation of fresh serum, physiological conditions will spontaneously establish themselves in the focus of infection. (2) Normal conditions may be restored by augmenting the transudation of lymph into the focus of infection, and displacing and expelling by this agency the ec-phylactic lymph. (3) Physiological conditions may be restored by processes of simple diffusion. In the early days of the war, when every wound was indescribably septic, what was required was not antiseptics, nor yet epi-phylactic treatment by vaccines, but efficient kata-phylaxis. In the putrid wound we had an ec-phylactic focus and therefore efficient drainage both of pus from the wound cavity and of ec-phylactic lymph from the surrounding tissues was needed, and for that reason the author recommended the use of hypertonic salt solution. In wounds we have two distinct types of exudate and two

distinct types of infection. In a "foul" wound we have an exudate with reduced anti-tryptic power and a multiform sero-saprophytic infection, whereas in a "clean" wound we have an exudate with undiminished anti-tryptic power and a purely serophytic infection. (The author gives the name *sero-saprophyte* to microbes, *i.e.* nearly all microbes, which can grow in blood fluids of reduced anti-tryptic power; those which can grow in unaltered blood fluids, the streptococcus and the staphylococcus, he terms *serophytes.*) We come, therefore, to a broad therapeutic principle, namely, that a "foul" wound can be rendered "clean" and a sero-saprophytic converted into a purely serophytic infection by bringing into the wound wholesome blood fluids, and that when this has been accomplished nothing is gained by flooding the wound with blood fluids, since this only supplies fresh culture medium for serophytes. Wright points out by means of experiments that the fact that the surface of a wound is not sterile is no reason for not suturing same if proper conditions for the leucocytes are provided. The three main sources of failure in the suture of an infected wound are: The leaving behind of corrupted pus; the leaving of dead spaces; default of leucocytic emigration into the wound. The weak point in our defense against microorganisms lies in the fact that the normal blood fluids provide a culture medium in which serophytic microbes can grow and multiply. Nature combats this by the development of increased anti-tryptic power in the serum, which renders it a less favorable culture medium for the serophyte. From experiments undertaken to determine this point, it was demonstrated that serum in septic infection acquires the power of killing serophytic microbes, and this of course brought up the issue of non-specific immunization. Since then further experiments have been made along this line. These researches have shown, and this has been demonstrated also by experience, that the time has come to discard the dogmatic belief that immunization must be strictly specific and that in case of failure we should endeavor to make immunization more and more strictly specific. Instead of this, we should proceed upon the principle that the best vaccine to employ is that which on trial gives the best immunizing response. This response should be tested *in vitro*, and this may become a practicable routine measure. Such a procedure would do away with the necessity of tentative experiments *in vivo*. When other methods of therapy fail, transfusion remains as a last resource. It must be remembered, however, that the normal blood fluids provide a favorable culture medium for the growth of saprophytes and that conditions where leucocytes are suspended in blood fluids are unfavorable to their bactericidal operations. It is not surprising, therefore, that simple transfusion in septic cases has failed. The situation would be changed, however, if the donor's blood could be immunized *in vitro* and the plasma rendered bactericidal for the microbe in question. This was done with markedly satisfactory results in one of the author's cases, and to this method Wright has given the name "immuno-therapy." In conclusion, Sir Almroth Wright points out the necessity for penetrating the principles that underlie the experience and knowledge gained during the war so that same may find practical application. He draws especial attention to the fact that the septic catastrophes of the earlier period of the war were due to an existing ec-phylactic focus in which all serophytic and sero-saprophytic microbes could freely multiply, and that this applies also to the open sloughing wound; that the failures which occurred when immediate primary suture was undertaken in presence of a streptococcus infection may be set down to default of leucocytic emigration and exudation of blood fluids into the wound, while the success of primary retarded suture in such cases is almost certainly due to free leucocytic emigration and the limitation of exudation; and that with respect to inoculation it is important to grasp the principle that, whether we are dealing with preventive or therapeutic immunization, we can expect results only when we have good epi-phylactic response in combination with efficient kata-phylaxis. To this combination is to be attributed the success that has attended antityphoid inoculation.

5. Recent Retrogressions in the Treatment of Fractures.—Major M. Sinclair draws attention to the appalling methods used and the terrible results obtained in cases of fractured femur by some of the German surgeons during the war. He does not attribute these results to lack of care on the part of the German surgeons and cites the case of one British officer who stated that the professor who attended him refractured his leg five times and set it again. The guiding principles of treatment seem to have been lack of extension and indefinitely prolonged immobilization. The majority of cases were treated on a trough-like metal back-splint with footpiece, the splint being of the same length in every case. When released, patients wounded in March were in the same state of splinting as those whose legs were broken in October. An original method of extension was tried on some cases. A sharp-pointed rigid metal hook, shaped somewhat like a note of interrogation, was put into the anterior surface of the tibia, with its straight unpointed end lying in the long axis of the bone and directed toward the foot. Another hook was passed in the opposite direction through the anterior superior spine of the ilium. A rope working over a pulley with a brick at the end was attached to each hook to establish the extension. A patient treated in this manner stated that every time his posterior wounds were dressed the weights were removed, and he noticed grating of the bones and shortening of the limb. Sinclair points out that had it occurred to the devisor of this apparatus that if he had raised the foot of the bed after applying the hook in the tibia, the body weight would have obviated the necessity of using the hook in the anterior superior spine, and at least one man's life would have been saved, since in one case the hook in the anterior superior spine was torn out and death occurred some days later from peritonitis. Three *x*-ray photographs are given which demonstrate the results of the German methods.

2. Medical and Surgical Work as a Prisoner of War.—Captain Alexander T. I. Macdonald draws attention to some of the ways in which the vaunted "efficiency" of the Germans differed from the British methods. Taken prisoner at a French dressing station in March, 1918, Captain Macdonald and a colleague were held prisoners all day treating British and German wounded alike. There seemed to be no medical officer with the German battalion, but only men belonging to the medical corps, or *Sanitäts* personnel. These men carried a small bag of dressings containing among other things a hypodermic syringe and solution of morphine, the former fitted into a bottle containing absolute alcohol to sterilize the needle. The injection of anti-tetanic serum, though regarded with suspicion at first, was for the most part submitted to by the Germans. Stretcher-bearing as carried out by the Germans was rather a crude operation, and in the case of a patient with a fracture must have led to extreme suffering. A ground sheet, slung on a pole borne on the shoulders of two bearers, contained the unfortunate patient. Duckboards and other substitutes were also used. The stretchers used by the Germans further back were heavier than the British ones and possessed the advantages of a head support, hinges for folding and sliding handles. The enemy medical officers remained relatively far back at the *Verbandplatz*, or dressing station. Here the author was struck by the meager supply of surgical material. Splints consisted of pliable wire—two thick pieces joined ladder fashion by thinner pieces, which were much too pliable for the thigh and leg, though often employed for this purpose. Volkmann's iron gutter was available for fractures of the thigh, but did not secure extension or immobility in transport as does Thomas' splint. Marching further back from the dressing station, the author passed a long line of enemy

transport ready to move; this consisted of a wonderful conglomeration of vehicles, including a brougham and pair, open landaus, Russian droshkies, etc. The ambulance transport consisted of small wagons capable of taking two stretcher cases, drawn by Russian or Rumanian ponies and flying a small Red Cross flag. The deficiency of motor ambulances was made up to some extent by attaching to each a string of two-wheeled trailers. Captain Macdonald and his colleague were then sent to one of the Bavarian *Krieyslazaretts* overflowing with British wounded who had received no further dressing than the first and were in urgent need of attention. They lay on beds, on stretchers, and on paillases on all available floor space, including that of the basement cellars. The operating and dressing room was dirty and sparsely furnished. A small coal stove served for the supply of hot water and the sterilization of instruments. A wash-hand basin was fitted with a supply of cold water only and was without waste pipe. Instruments were few in number and partly denuded of plating; this, however, was remedied later and a gas stove and electric light provided. The most rigid economy was entailed in the use of surgical materials. Soap powder with sand, powdered washing soda, cakes of clayed earth and fine gritty material admixed with soap were obtainable at times; at other times there was no soap of any kind and one had to trust to prolonged immersion in sublimate solution to afford a degree of surgical cleanliness. In doing dressings, therefore, extensive use was made of forceps and the wounds were not touched with the fingers. Rubber drainage tubes were scanty and were not supposed to be cut, if not of suitable length. Bandages were mostly of paper. For securing splints, roller bandages made from lace curtains or cotton dress materials were used sparingly and were collected from time to time, washed, and rolled again for use. A substitute for cotton wool was provided in the shape of *Selkstoff*, made from paper. A substitute for benzol was used to prepare the skin, with tincture of iodine for use as a final application. Open wounds were cleansed by irrigation with diluted hydrogen peroxide. Moist dressings of dilute solution of aluminum acetate on lint covered with jaconet were used for cellulitis. There was no shortage of anesthetics. In fractures of the femur, extension from a clamp applied to the skin over the lower end of the bone just above the condyles on either side was much employed by the Germans; this resulted in the skin over the points of pressure becoming septic and sloughing, with great deformity and shortening. The author points out that among the medical cases a variety of nephritis and a condition (the result of slow starvation) characterized by weakness, shortness of breath, emaciation, edema of feet and legs and anemia was frequently met, as was influenza, often followed by pneumonia. Diarrhea and dysentery were rife; impetigo, furunculosis, and scabies were common. Pneumonia was rapidly fatal in the poor starved men who often remained at the camps for days without treatment before admission to hospital. Conditions were particularly bad among the newly captured men, who were not only starved but also dirty and ill-clad, having disposed of part of their clothing for food. These men received no Red Cross parcels, and their condition was very different from those in the next camp who received food, soap, and warm clothing from home. Drugs, chiefly in tablet form, were of good quality. The hospital dietary was divided under three main heads: the ordinary diet consisting of half a bowl of soup, replaced by boiled rice with a spoonful of dried fruit on Fridays, black bread, jam, so-called tea or coffee, with occasionally a small piece of sausage for supper, or bread and meal gruel. The black bread was sour and indigestible and contained sawdust, as the loaves were rolled in sawdust. Form 2 was similar to the ordinary diet, but three thin slices of white war bread spread with margarine were given instead of the black bread, and the soup was rather more digestible. A small amount of milk, an egg, which was usually bad, or a glass of wine could be ordered as hospital extras. Form 3 was supposed to be suitable for diarrhea cases and consisted of thin gruel, puree of potatoes, etc. As the quantity of white bread given was insufficient, patients as a rule asked to go back to the ordinary diet. The beds in the wards were of wood and were roughly constructed. Mattresses were made of paper sackcloth filled with wood shavings over which a sheet was placed. In helpless patients bed sores were inevitable. No rubber cushions or water beds could be obtained and a shift was made with rings of straw covered by bandage. Clean bed linen was rare and there were no means of disinfecting clothing. Baths were given to walking cases and personnel at a large factory in the town, which had been fitted with bathing and disinfecting station. The conservancy system in the hospital was extremely crude; the latrines were a source of nuisance and in the summer flies were very troublesome. At Conde, where the author spent several days at a prison on the French frontier, a French lady succeeded in smuggling to them bread, lard, soup, and ragout from time to time. From there Captain Macdonald was sent from place to place, the last stage of his journey coinciding with the outbreak of the revolution. On Christmas Day he left Germany with, as he says, a higher opinion of British organization than ever before.

1. The Present Status of the Cancer Problem.—L. Duncan Bulkley says that according to the yearly mortality tables issued by the United States the death rate of cancer has steadily risen, with a fearful certainty, almost 30 per cent. since 1900, while that from tuberculosis has fallen in the same degree, 30 per cent. during the same period under careful medical surveillance. Moreover, during 1915, when surgical activity was at its highest, owing to the active propagandism for early and radical surgical removal the year before, the increase in the death rate from cancer was over double the average increase of the five previous years. It is acknowledged by all that under the past views as to the local nature of cancer and its treatment by excision the ultimate mortality of the disease is 90 per cent. of all those once attacked, and yet the profession and laity go blindly on with the idea that surgery offers the only hope of reaching cancer. The value of the *x*-ray and radium may be serviceable in certain cases to remove actual lesions, but their value is extremely limited and can no more reach the real cause of cancer than can surgery. While the laboratory has not at all solved the cancer problem, it has contributed not a little toward establishing negative facts, and also some positive which lead up to a more correct understanding of the real nature of the disease and its prevention and treatment. The best authorities agree that: 1. Cancer is not contagious or infectious, although certain new growths can be inoculated in some animals; but human cancer cannot be transplanted on animals, and no surgeon, nurse or pathologist has been infected. 2. Cancer is not caused by a microorganism or parasite, although many microorganisms have been found in cancerous lesions, but none of them have been established as a cause. 3. Cancer is not wholly the result of traumatism, although local injury may induce its localization in some particular region. 4. Cancer is not to any appreciable degree hereditary, although some tendency in that direction has been found in certain strains of mice. 5. Cancer is not due to occupation, although it is more common in some pursuits than in others. 6. Cancer is not altogether a disease of older years, although its frequency is influenced by advancing age. 7. Cancer does not especially belong to or affect any particular sex, race, or class of persons. 8. Cancer is not confined to any location or section of the earth, but has been observed in all countries and climates. Some positive results of research are encouraging. 1. The local mass which we call cancer represents but a deviation from the normal life and action of the ordinary cells of the body. 2. Certain changes have been demon-

strated microscopically in the polarity of the cells about to become cancer-genetic, with altered relations of the centrosome to the nucleus, all being influenced by disordered metabolism. 3. Much in laboratory studies on the biochemistry of cancer has confirmed the clinical and statistical observations fast accumulating. 4. The blood in advancing cancer shows many manifest changes, indicating vital derangement of the organs which form blood, and which therefore control the nutrition of cells. 5. The secretions and excretions of the body in the early and late stages of cancer have been shown to exhibit departures from normal which are of importance in its causation. 6. Cancer tissue has been shown to contain an element which is poisonous to animals and which probably hastens the lethal progress of the disease. 7. Diet has been repeatedly shown by the laboratory to inhibit the development of inoculated cancer in mice and rats. 8. As laboratory and other research have eliminated the local nature of cancer, they have also established certain medical aspects of the disease which are of the utmost importance. Finally clinical and statistical studies have abundantly confirmed the correctness of the internal basic cause of cancer. 1. The mortality from tuberculosis has steadily and greatly diminished under careful medical guidance, while that from cancer has increased in almost the same ratio, without proper medical care. 2. Cancer is almost absent among aborigines, living simple lives, largely vegetarian, but has increased steadily among them in proportion to their adoption of the customs and diet of so-called modern civilization. 3. Self-indulgence in eating and drinking, with indolence, has been shown by many to result in increased cancer mortality. 4. The increased consumption of meat, coffee, and alcohol has been shown by statistics from many countries to be coincident with increase in cancer mortality. 5. Great nerve strain and shock have repeatedly been shown to affect the development of cancer, and the enormous nerve strain of modern life seems to be effective both through metabolic derangement and by direct action on living cells. 6. While it is impossible to explain just how disordered metabolism induces cancer-genetic changes in cells, it is no more difficult to believe that it does so than it is to understand the intrinsic cause of arterial degeneration, bone changes, obesity, etc., which are recognized as due to metabolic derangement. 7. The spontaneous disappearance of cancer, as occasionally reported, shows that conditions of the system may arise which are antagonistic to carcinosis. 8. Finally, the complete removal of cancerous lesions, in various localities, by most careful dietary, hygienic and medicinal measures alone, without surgery, *x*-ray or radium, as has been repeatedly reported, shows that there is a constitutional basic cause, of which the local lesion, which we call cancer, is but the product.

2. A Study of the Digestive Psychoses.—George M. Niles draws attention to the fact that "nutritional neurasthenia," "Americanitis," "morbus strenuosus," and other catchy phrases owing to the various disturbances of digestion and nutrition due to psychic disquietude might lead one to surmise that this were a modern disease, an outcropping of twentieth century civilization, and one of which we should be mournfully proud. Psychic indigestion is by no means of recent discovery, but belongs to that category which the man of wisdom had in mind when he remarked, "There is no new thing under the sun." Up to the past few years little weight was accorded the factors responsible for the excitation or inhibition of these juices, apart from the chemical and mechanical. It seems that the well considered words of old Solomon were unheeded, "A merry heart doeth like good medicine," and "Better a dinner of herbs where love is than a stalled ox and hatred therewith." For many centuries in the discussion of physiological digestion, as well as of pathological indigestion, the influence of the emotions received scant attention. Briefly stated, when food is taken the secretion first started is due to the sensation of eating and of taste; that is, it is a psychic secretion. The cases of true psychic indigestion are almost invariably found in the middle years of life, among those who think for themselves and others. The nerve centers of young children are less impressionable to emotional excitants; and when the "lean and slippered pantaloon" has been reached, the waning digestive powers, in their halting efforts to produce needed bodily energy, have no time to play fantastic pranks on the "commissary department." Digestive troubles in these two extremes of life are generally due to dietetic errors, while in old people organic and malignant maladies play an important part. Seldom do we find psychic indigestion among those who earn their bread by manual toil, except in brief explosions due to some violent mental irritants. As to the treatment of gastrointestinal psychoses, it must embrace more hygiene than dietetics, more suggestion than drugs. It is among these patients that the personal equation of the medical attendant counts for much; for the cheery optimist who can instill confidence and hope into doubting and despondent hearts is the one who gets results. Therapeutic cognizance must be taken of tangible bodily ailments, and appropriate medication has its important place here as in other more material troubles. He, however, who attempts to reach these shifting and evanescent psychoses by a hide-bound system of dietetics, stomachics, digestants, tonics, or any other adventitious aids to digestion will be foredoomed to failure. Another therapeutic measure which often proves a benefit is a radical change of occupation or environment. It is noticeable that one's digestion is always good on a holiday, and many people find that they can with impunity eat articles of food while on a vacation or pleasure trip which would profoundly disturb them at other times. It is worth the thought and time of the physician to regulate for good, if possible, the environment of every chronic dyspeptic; otherwise many a well-chosen prescription will come to naught in the presence of petty worries and repinings that seem to act with malign force on the digestive organs. When, therefore, by means of both material and psychic therapy, intelligently and energetically applied, the minds of these sorrowful invalids are taken from their stomachs; when their daily thoughts are lifted out of their introspective grooves; when their ill-nourished bodies are furnished with sufficient food, and their dessicated tissues are laved with an abundance of water, then can the vicious circle be broken and the psychic aids to digestion resume their normal place in the bodily economy.

8. Concerning Ureteral Stones: The Removal by Non-Cutting Operation.—E. P. Merritt states that most authorities are of one accord that the ureteral stone formation takes place in the kidney pelvis, which, he thinks, is correct in a large majority of cases. The diagnosis, after centralizing our minds on ureteral stone, would be practically easy if all the stones would show under the exposure of the *x*-ray. Thanks to the rays, a very large percentage does show; but now and then a pure phosphatic or uratic stone will not show. Then if the clinical symptoms point to stone, shall we say "negative"? Not until the cystoscopic methods have proven so, namely, obstruction to catheters and negative findings per wax-tipped catheters. Shadows resembling ureteral calculi in the ureteral region are not always to be taken seriously until further investigation. For instance, pathological mesenteric glands and phleboliths give shadows that are misleading. The differential diagnosis is made easy by inserting an iron oxide catheter into the suspected ureter, having a roentgeno-

gram made and noting the obstruction met and the distance from catheter to shadow. Merritt's non-surgical method for removing ureteral stones is as follows: Dilate the ureter below the stone with ureteral dilators. After the introduction of papaverin or novocain, 2 to 4 c.c. of 2 per cent. solution, the catheter is withdrawn so that the ureteral walls may be infiltrated thoroughly. If a small ureteral orifice obstructs, then use ureteral scissors to cut the meatus to desired size. After this pass a stiff catheter to or beyond the stone if possible. Inject then from 2 to 4 c.c. of sterile olive oil. Of late Merritt has injected a few drops of 10 per cent. argyrol or silvol afterward for the antiseptic value it possesses, possibly reducing soreness from manipulation. The patient, if not in pain, may sit up. If in pain, large doses of morphine, hot applications, and an abundant intake of fluid are indicated. This procedure is employed at intervals of three days if the condition of the patient will permit. The average number of times for the removal has been three with Merritt. If in watching for a "big stone" we do not see it pass, we should not be discouraged, as it will ofttimes break up and come out in small particles; or there may be more blood clot sometimes than there is stone. This is especially true of the phosphatic type. It is a good idea to be convinced of the absolute removal by another ureteral examination. This method is convincingly reasonable and safe, even if we do not succeed every time. There is no harm done, and in the majority of cases, especially selected cases, this method saves a cutting operation.

February 17, 1919.

Has Normal Horse Serum an Action on Experimental Injection of the Guinea-Pig with the Diphtheria Bacillus?—E. Friedberger says that, on account of von Bingel's recent article in which is discussed the really specific efficacy of antidiphtheritic serum, he feels compelled to again revert to this question with all its details. The doubts which at first existed at the onset of the use of antidiphtheritic serum have been forgotten and covered by the almost universal enthusiasm which has hailed this therapeutic measure. At the present time it may be asked whether or not the serum does not owe a large part of its effectiveness to a happy combination of circumstances. Diphtheria, an epidemic disease subject to great periodical fluctuations (Rokitanski declared, in 1847, that it was a "French invention"), was in 1894—the date of the appearance of serotherapy—in a phase of decline. It can be proved that the rapid decrease in the extension of the disease had already begun some time before this memorable year. The various statistics invoked in favor of antidiphtheritic serotherapy are hardly univocal, and the majority are perverted from special circumstances. Thus, the establishment of bacteriological institutes has unquestionably greatly multiplied the diagnoses of simple diphtheritic angina, and for this very reason the percentage of serious cases has been improved on. These disturbing perplexities have led the writer to experiment again, particularly from the viewpoint of comparison between the action of antidiphtheritic serum and that of simple horse serum. By a series of carefully conducted experiments the writer shows beyond question that antidiphtheritic serum has a fully justified reputation. With equal doses he cured experimental diphtheria, while the animals died when horse serum was used. However, the writer states that although the specific serum may be regarded a curative in the experimental form of the disease, the question of its clinical value is of quite another order. The injection of cultures of Loeffler's bacillus in the guinea-pig only distantly reproduces the conditions of human diphtheria, so that the question can only be definitely settled by clinical observation and statistics carefully made on a large scale.

Münchener medizinische Wochenschrift.

February 14, 1919.

The Reaction of the Circulatory System in Fatigue.—O. Bruns has studied both the heart and peripheral vessels in states of bodily fatigue and the results recorded by numerous plethysmographic charts. The heart in fatigue offers a decreased tonus, that is to say, an increase in both its systolic and diastolic dimensions, while at the same time both the pressure and amplitude of the systoles remain constant. Some irregularity of the contractions was also noted. In progressive body fatigue an increasing atony of the cardiac walls takes place. In the vessels local muscular fatigue produces a decrease in the vasomotor reactions to thermic stimulation. On the other hand, central influences (mental calculation, the sentiment of joy or displeasure) produce an equal reaction in both the fatigued limb and the fellow member which has not been tired. From the qualitative viewpoint, the vascular reactions in the state of fatigue are normal, and only a deviation of the reaction takes place in the following circumstances: A tired subject is ordered to resume work, in which case instead of the usual vasodilatation taking place before muscular effort occurs, there is a vasoconstriction which the writer attributes to a strong feeling of resentment experienced by the subject when receiving the order to work.

The Offspring of Soldiers on Leave and the Solution of the Problem of the Sex.—F. Lenz alludes to Siegel's study on the subject of sex in which the latter maintains that the sex of the infant depends upon the time of conception, boys being the rule in postmenstrual conception. The writer criticizes Siegel's theory and remarks that such results are not in accord with what we now know of "the science of heredity." It is known, he says, that the sex is determined by the spermatozoid, each of which possesses a determined sexuality. The proportion of sexes, therefore, can only be influenced by those factors which favor fecundation by male elements. Such are difficulties in conception, primiparity, youth of the mother, and all debilitating factors.

Deutsche medizinische Wochenschrift.

February 18, 1919.

The Theory and Technique of the Serologic Diagnosis of Syphilis.—E. Meinicke exposes theoretical views and experimental findings on this subject. The various modern procedures (Wassermann, Sachs-Georgi, Meinicke, etc.) are all reactions of precipitation which are represented by various methods such as the hemolytic system, the lipoids or sea salt. The development of these procedures has resulted in marked progress in the domain of serologic diagnosis. The writer shows that these different methods are variously influenced by added factors, such as bile, tuberculin, etc. Their concordance cannot, therefore, be absolute in every case, so that an ideal method is yet to be found which shall depend entirely upon factors of syphilitic origin.

The Reaction of Precipitation in the Diagnosis of Syphilis According to Meinicke and Sachs-Georgi.—F. Reich has experimented with both methods and compared their results with those obtained by the Wassermann. The Sachs-Georgi technique (a mixture of inactivated serum with the autogen in presence of an exactly determined quantity of cholesterin) is the simplest and also presents a much more constant concordance with Wassermann than does Meinicke's reaction (precipitation of any serum in the presence of an alcoholic extract of organs, the precipitate being insoluble in a solution of sea salt and in normal sera, but soluble in syphilitic serum; the reaction consequently takes place in two stages). For this reason the Sachs-Georgi reaction represents the greatest progress realized during the past few years in the domain of syphilitic serology.

Active Immunization in Hay Fever.—K. Eskuchen considers the treatment of this affection with injections of pollen toxin, according to the procedure of Noon and Freeman (*The Lancet*, 1911), as the best. The treatment can be intensified by the internal exhibition of calcium chloride. The technique of the procedure requires detailed study; the initial dose should be estimated after the cutaneous and ocular reactions have been obtained, and the doses injected should be slowly but progressively increased. The writer reports a very instructive case.

Wiener medizinische Wochenschrift.

February 15, 1919.

Cutaneous Lesions from Solar Rays.—G. Nobl offers a general study of this group of affections. He studies the indispensable part played by the presence of certain substances of alimentary or internal origin, but in a changed (spoiled) state, in pellagra and divers hematoporphyrins in the dermatosis called "estival hydroa, sen vacciniform" by Bazin, etc. The writer records an example of familial distribution of the latter affection. The sensibilization of the skin to rays of light may be produced experimentally in white mice by several products similar in nature, such as chlorophyl, bile, or hemoglobin derivatives. One writer has injected 20 centigrams of hematoporphyrin into his arm and afterward presented serious accidents of hypersensibility after exposure to light. The treatment of vacciniform hydroa and similar pathological conditions consists, naturally, in protecting the parts from solar rays, as well as by the employment of various well-known local applications.

The Influence of Influenza on the Female Organs of Generation.—R. Franz has met with disturbances of the menses in women with influenza, particularly metrorrhagia and menorrhagia, but has been unable to establish a relationship between the intensity of the influenzal process and the gravity of the menstrual disturbances. In pregnancy this tendency to hemorrhage may result in miscarriage or premature labor. In the case of the genitalia in the female, influenza produces the same hemorrhagic tendency as it does in other viscera.

Gazette des Hôpitaux.

March 8, 1919.

Kernig's Sign in True Typhoid Fever.—Audibert and Nalin of Marseilles discuss at length the occurrence of this meningeal symptom in sepsis due to Eberth's bacillus. Kernig, the Russian clinician, first described his sign in 1884. He first noticed in the course of meningitis a peculiar rigidity in the lower extremities. As a consequence of such rigidity, if the victim sit on the side of the bed the trunk will be unable to make an acute angle with the thighs. If the situation is forced the legs become half flexed on the thighs. With this sign we find rigidity of the nucha and trunk. From that period Kernig's sign has often been encountered in meningeal affections. However, it is not always to be elicited in meningitis, while on the contrary it has been seen in nonmeningeal affections and as a result has gradually lost pathognomonic significance. As far back as 1899 it was seen in typhoid without much evidence of meningeal implication. On the other hand, in true typhoidal meningitis it was as a rule present so that the sign became of especial value in typhoidal meningitis. In miscellaneous typhoid taken as it comes, the per cent. with a Kernig varies extremely—from 10 to more than 50 per cent. The authors have especially studied the evolution of the sign, the diagnostic and prognostic significance, the relations between the sign and the lumbal punctates, etc. The final conclusions are as follows: Kernig's sign is very frequent in affections due to Eberth's bacillus—in the author's experience in over half of all cases. It appears at the outset of the disease and does not disappear as a rule until convalescence. It is rarely absent in the severe form (save in adynamia after the system no longer defends itself against the disease), but is often encountered in the mildest forms in which there is no participation of the nervous system. Its explanation is to be sought in the action of the disease toxins on the cerebrospinal motor system, but it occurs in association with perfectly normal cerebrospinal fluid. In general it is indicative of a sepsis or blood state and not of a special state of the cerebrospinal fluid.

Le Progrès Médical.

March 1, 1919.

New Researches on Filtrable Viruses.—Bernard states that our knowledge of these substances has been negative, for we have no information beyond the fact that the microorganism is too minute to possess characteristics. The strangest phenomenon has been the inability to obtain cultures. It is true that now and then a filtered virus is found to contain some very minute organism and cultures have been obtained on anaerobic media and inoculated successfully. Such results have been the exception, however, and have never been obtained for the endemic diffusible affections, measles, mumps, etc. Positive finds have been limited to strains of influenza, save that two war maladies, trench fever and nephritis, which are quite unrelated to the great epidemic infections, appear to be caused by filtrable virus. The chief interest at present centers in influenza. Both English and Brazilian authors have found extremely minute cocci in influenzal patients in the blood and various secretions, but it is not certain that the organisms are the same. In the British army the patients investigated showed the presence of a coccus in all cases examined, although the numbers tested were small. The omnipresence of this germ was striking and it seems to have been discoverable almost anywhere in the body—cerebrospinal fluid, enlarged lymphnodes, etc. When inoculated within the dura or veins of the guinea pig and monkey the animals presented symptoms of grippe and autopsy showed extensive hemorrhagic pneumonia and lesions of some of the large viscera which comprised congestion and hemorrhages. The first inoculations did not cause death but passage through one animal increased the virulence to the point of causing a fatal termination in some of the material.

Correspondenz-Blatt für Schweizer Aerzte.

March 8, 1919

Hoffa's Disease.—Dubs gives a succinct account of traumatic increase of adipose tissue in the knee joint. We have not heard much of this affection since the death of Hoffa. The author has gathered together and analyzed all accessible data and reaches the following conclusions: There is invariably a history of traumatism, either one violent injury or repeated minor injuries. The violence need not be external but may comprise intrinsic lesions of various character, including mere irritation of foreign bodies. The lesion is an inflammatory hyperemia of the fatty tissue in the alar folds and ligamentum mucosum. In other words, the subpatellar fat is gradually changed to firm fibrous tissue. The initial lesion is believed to be a hemorrhage—numerous minute hemorrhagic foci which are due to trauma and give the impetus to the small cell infiltration. The latter is increased and generalized as a result of the continuous irritation. The new formation of fibrous tissue invests islets of the remaining fat. When a knee joint is opened we see a yellowish red, firm, cock's comb-like or racemose mass replacing the subpatellar fat, enlarged, with processes which penetrate into the joint spaces. Such a mass may reach the size of a hen's egg. The results of this condition are atrophy of the quadriceps and pseudofluctuation at either side of the patella with doughy feel, which is sometimes quite sensitive to pressure. Passive motion and locomotion are largely unaffected. The *x*-ray reveals the presence of the mass as a faint shadow, but the value of this in diagnosis is questionable. Conservative measures usually suffice for treatment but orthrotomy is sometimes necessary. Under the former may be mentioned massage, hot air, sandbaths and compression.

A Grip-Like Infection in the Fall of 1917.—Schittenhelm and Schlecht, connected with a German army on an Oriental front, noted the presence of an affection which began August 1 and lasted until the middle of October, 1917. Three units seated in different regions of a wide geographical area were attacked simultaneously in epidemic form. The onset was sudden, the symptoms those common to acute infections and the duration from 7 to 9 days. The picture was at times atypical and in small percentages unusual manifestations were seen, as eruption, diarrhea, etc. Aspirin was very serviceable. There were 4 possibilities—malaria of a remittent type, influenza, dengue and some unknown affection.—*Office International d'Hygiène Publique.*

Book Reviews.

PAPER WORK OF THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. A Guide for Administrative Work. By RALPH W. WEBSTER, M.D., Ph.D., Major Medical Corps, U. S. Army; Instructor, Basic Military Course, and Adjutant, Camp Greenleaf, Chickamauga Park, Georgia; Formerly Instructor at the Medical Officers' Training Camp, Fort Riley, Kansas; Author of Diagnostic Methods, Chemical, Bacteriological, and Microscopical. Approved for Publication by Direction of the Surgeon General of the U. S. Army. Price, $5.00. Philadelphia: P. Blakiston's Son & Co., 1919.

THIS book is intended for the instruction of the medical officer who has had hitherto no experience of military matters. With this object in view the most important papers dealing with organization have been brought together by the author. Extracts have been freely made from all works bearing on the subject of military duties and regulations, and the book is in effect a compilation of such material as is likely to be useful, arranged in a handy manner. The work was called for and filled a want and reflects much credit upon the industry of the author.

MASSAGE AND THE ORIGINAL SWEDISH MOVEMENTS, Their Application to Various Diseases of the Body. Lectures Before the Training Schools for Nurses Connected with the Hospital of the University of Pennsylvania, German Hospital, Woman's Hospital, Philadelphia Lying-in Charity Hospital, the Philadelphia Polyclinic and College for Graduates in Medicine, and the Kensington Hospital for Women, Philadelphia. By KURRE W. OSTROM from the Royal University of Upsala, Sweden. Eighth Edition. Revised and Enlarged with 125 Illustrations. Price, $1.00. Philadelphia: Blakiston's Son & Co.

MASSAGE and the Swedish movements are recognized as a valuable part of therapeutics and as essential in the treatment of certain conditions. The late Mr. Ostrom might be termed the high prophet of these methods and his book supplied an excellent exposition of the same. However, as this is an eighth edition, it will suffice to say that the revision has been ably done by Mr. Silfverberg, who has followed closely the notes left by Mr. Ostrom, with the exception of those on dislocations, the article on which is written from his own viewpoint.

CLINICAL MEDICINE FOR NURSES. By PAUL H. RINGER, A.B., M.D., Member of Staff of the Asheville Mission Hospital, Asheville, N. C., and of Biltmore Hospital, Biltmore, N. C. Illustrated. Price, $2.00. Philadelphia: F. A. Davis Company, 1918.

OF recent years nurses have been called upon to do some of the work which used to fall almost wholly within the sphere of the medical man or surgeon. This being so, it is essential that they shall have a fair knowledge of clinical medicine. The lectures by Dr. Ringer now embodied in book form were delivered with the view of imparting to nurses such knowledge and he seems to have succeeded well in his self-imposed task.

AUTOTHERAPY. By CHARLES H. DUNCAN, M.D., Discoverer and Founder of Autotherapy; Formerly Mechanical Engineer of the Illinois Steel Company; Co-Founder of the Volunteer Hospital; Attending Surgeon and Genito-Urinary Specialist, Volunteer Hospital, New York City, 1905-1914; Honorary Member Veterinary Medical Association, New York. Price, $5.00. New York: Published by Dr. Charles H. Duncan.

DR. DUNCAN during the past few years has written widely in the medical journals concerning his method of autotherapy, and consequently medical men generally are conversant with his views. *Similia similibus curantur* applies to some extent to the doctrine of Duncan. Although not exactly founded on the principle of like being cured by like, the idea of curing disease with its own poison comes within much the same category. Autotherapy appears to be a logical development of vaccine treatment, and if the clinical results therefrom are as good as they are stated to be, the method constitutes a great advance. Moreover, it is claimed to be harmless or, at any rate, not dangerous. Autotherapy promises much, but, like everything new, it must be tested for a long time ere the statement can be made that it is a success.

AMERICAN RED CROSS TEXT-BOOK ON FIRST AID AND RELIEF COLUMNS. A Manual of Instruction on How to Prevent Accidents and What to Do for Injuries and Emergencies. By Colonel CHARLES LYNCH, Medical Corps, United States Army. Prepared and Endorsed by the American National Red Cross. Second Edition. With 52 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1918.

THIS new edition of a very valuable work and one which has amply demonstrated its usefulness has been thoroughly revised and considerably enlarged. It is a *vade mecum* on the subjects with which it is concerned and the author is to be congratulated on the manner in which he has presented and tabulated the contents of the book.

THE MEDICAL CLINICS OF NORTH AMERICA. Volume 2, Number 3, November, 1918. Price per year, $10.00. Published bi-monthly. Philadelphia and London: W. B. Saunders Company.

THIS is the "Philadelphia Number," the contributions being from the various clinics in that city. About one-half of the volume is given over to the discussion of the various phases of the influenza epidemic and the articles are at once interesting and informative. The other articles are upon many and varied subjects. Rehfuss's discussion of the treatment of biliary affections is perhaps the most interesting, though some of the others are of as much value. The number is an exceedingly interesting one, and in its nearly three hundred pages covers a wide range of medical conditions.

STUDIES FROM THE DEPARTMENT OF MEDICINE. Cornell University Medical Bulletin. Vol. VIII, No. 3, January, 1919. New York: Published by Cornell University.

THIS volume consists of a collection of twenty-four reprints of studies from the Department of Medicine, Therapeutics, Ophthalmology, Obstetrics, Dermatology, and Radiology, which have appeared in medical journals during the period 1913 to 1918. They represent investigations covering a wide range of subjects and offer concrete evidence of some of the research activities carried on by the personnel of this institution. It is a very creditable publication.

PHYSICAL AND OCCUPATIONAL REEDUCATION OF THE MAIMED. By JEAN CAMUS, with the collaboration of A. Nyns, Bourrillon, F. Terrien, E. Fontaine, Nové-Josserand, Bourget, Boureau, P. Larue, A. de Mazières, E. Leroux, P. de Cabaussel, E. Voron, J. Nanot, P. Lindemans, Belot, Privat, H. Nepper, and C. Vallée. Authorized Translation by W. F. CASTLE, Surgeon, R. N. With articles on British Institutions by Sir ARTHUR PEARSON, Bart., Margaret Lale, and DUDLEY B. MYERS. Price. $2. New York: William Wood & Co., 1919.

THIS book is the most complete work on reeducation of the disabled by war in France, and in saying this it may also be inferred that it is one of the best works on the subject in the world. All the men engaged in the writing thereof are authorities. The appendix is a valuable addition as it contains chapters on St. Dunstan's by Sir Arthur Pearson, on Lord Robert's Memorial Workshops by Miss Margaret Lale; on results obtained at Roehampton by Mr. Dudley S. Myers, and on the chief types of artificial limbs in use in England.

DIABETES AND ITS DIETETIC TREATMENT. By B. D BASU, Major, I.M.S. (Retired). Ninth Edition. Revised and Enlarged. Price, One Shilling. Allahabad: The Panini Office, 1918.

THIS book advocates the treatment of diabetes by a dietetic regimen in which vitamines are present in sufficient quantities. Dr. Basu, therefore, urges on the medical profession the importance of the study of the question of vitamines in the pathology and treatment of diabetes.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 20, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

Experiences in France with Surgery of the Genito-Urinary Tract.—Major A. RAYMOND STEVENS, Med. Corps, U. S. Army, presented this paper, the purpose of which, he stated, was to give a notion of the infrequency of gunshot wounds of the urinary tract in war and to report some personal experiences. For well over a year he was with the British Army, as a member of U. S. Base Hospital No. 2, engaged in general surgery, but was also given the care of all the genito-urinary injuries that were admitted to the hospital. No venereal cases were included. He spent two months in British Casualty Clearing Stations during periods of military activity, and in September, 1918, he was sent to the Mars-sur-Allier Hospital Center, and a few weeks later moved to the Center at Mesves, and was also attached to Base Hospital No. 67. He expressed himself as particularly impressed by two facts concerning war wounds of the urinary tract: first, the relatively small number of cases in the hospitals and, second, the high mortality of these. The relative rarity of kidney and bladder lesions was perhaps explained by the obvious possibility of frequent fatal hemorrhage following wounds in these parts. Various groups of statistics showed the kidney involved in from 4 to 9 per cent. of penetrating abdominal wounds, and the bladder in from 4 to 7 per cent. The number of men with abdominal injuries who lived to reach a hospital was only a small fraction of the total number admitted. One American surgeon in a general operative experience, extending over a period of five months in the Front Area, met with but a single kidney wound. Another whose evacuation hospital work totaled 400 cases and included a good share of abdominal work found no wound of either bladder or kidney. The writer's experience in this respect was very similar to that of others. Cases cited emphasized the importance of immediate suture of urethral injuries when possible. This procedure gave excellent results in many cases, and at the worst the resultant scar would be much smaller following suture than would be the case otherwise. At the base hospitals, as would be expected, the proportion of urinary wounds was even smaller than in the hospitals of the forward areas. At the Mesves Hospital Center the number of patients in the hospitals at one time totaled nearly 23,000, yet he did not see and did not learn, in response to direct questions put to the chiefs of all the surgical services, of a single case of wound of the kidney at this center. The mortality, as before stated, of patients with wounds of the urinary tract in the war was very high. A recent French publication giving collected statistics stated that non-complicated bladder wounds had resulted in a mortality of 56 per cent., and of fifteen cases with coexisting intestinal wounds but one lived. He had records of eleven patients with wounds of or adjoining the bladder, and to his knowledge at least six of them died. Not only were intraperitoneal and pelvic complications accountable for the very heavy mortality of bladder cases, but wounds in other parts of the body handicapped the patient seriously, and materially reduced his chances of recovery. Speaking of suprapubic wounds, Dr. Stevens said that it was advisable as a rule to close a bladder wound occurring in the peritoneal surface, but to drain an extraperitoneal opening. A deviation from the latter part of this rule might impair the patient's prospects, as was illustrated by several cases cited. Another point emphasized was the importance of removing all loose bits of bone in complicating fractures of the pelvis. It was observed that penetrating wounds of the buttocks were notoriously full of grave possibilities, one of which was a bladder or ureteral injury. The bladder complications of gunshot wounds of the spine had interested urologists very much. The behavior of the bladder varied greatly in different instances, but there was usually a period of retention before incontinence set in and different devices had been employed to overcome this retention. They had had eighteen or twenty such patients, and tried in different instances infrequent catheterization, suprapubic drainage in some persistent cases, and the "do-nothing plan," so strongly advised by some English surgeons. The latter, he was convinced, was not of universal application, but it was probably the ideal treatment where it could be borne, depending, as it did, entirely on the overflow drainage of the bladder. Any harm done the kidney by a continuously large amount of residual urine in the bladder probably represented a smaller risk than that of urinary infection following catheterization in spine cases. Dr. Stevens referred briefly to the subject of hematuria in soldiers and stated that many cases were cystoscoped with the amazing result that over 90 per cent. of them represented types of what was rather loosely termed "War Nephritis."

Experiences of a Urologist with the Fighting Forces in France.—Lieut.-Col. EDWIN BEER, Medical Corps, the United States Army, spoke informally of his personal experiences in the war zone. He said that when asked to present a paper he had declined because he felt that he did not know enough about the subject assigned to him. When one did surgical work in the forward war zone he knew nothing of what happened to the cases afterward, so he thought it was a mistake to publish results of that work. Furthermore, he said that he made but a poor pretense at being a urologist in connection with his war work, for he had not used a cystoscope and to his mind a urologist without a cystoscope was almost inconceivable. One of the most important contributions to modern medicine was the carrying out of prophylactic measures against venereal disease in the army. These prophylactic measures which had proved so effective in our army would undoubtedly soon be adopted by foreign armies. At one time Great Britain had five divisions laid up with venereal diseases, while owing to the adoption of prophylactic measures our armies had suffered no such crippling of their fighting efficiency. But the prevention of venereal diseases among our fighting forces was only one of the important advances accomplished in the recent war. Another important advance in the provisions for the care of our soldiers was the introduction of surgical teams. These operating teams were usually made up of one surgeon in chief, two assistant surgeons, two nurses, and two orderlies. When there were sufficient teams on the slate there was no need of overworking anyone even at the front, but the surgical teams were not completed until the fall of 1918. With the general shortage of surgeons on the other side, he had never been able to understand why it was that men who wanted to do surgical work were sent to camps here and stalled, spending their time in learning the duties of the enlisted men, the laws of Court Martial, the army paper work, etc., when it would have been much better to have sent them overseas in 1917, where they could have cooperated with the French and British and learned the surgical game as it was played in the fighting areas. Another excellent development in the A. E. F. was organized at Toul, near St. Mihiel; this was a training school for surgeons, which was run by very excellent surgeons, and here men not familiar with military surgery were trained for service. Military surgery, as they all knew, was quite different from civilian surgery, and an American surgeon, no matter how well versed in civilian surgery, could not rush immediately to the front on landing in France, but first should undergo a course of training in military surgery. He had to learn how to handle war wounds and what cases not to operate upon. The tendency in the war was to operate on every case. Military surgery was peculiar in that the object set before the surgeon was complete excision of all traumatized tissue and the removal of all foreign bodies, bits of shell, metal, clothing, etc., because experience had shown that if any traumatized tissue remained gas gangrene almost invariably followed. At the front the operating was done in tents while the armies advanced, there being ten operating tables placed side by side in such a tent. Each surgeon ran two tables and got all kinds of cases, wounds of the brain, chest,

abdomen, and extremities, and while there was a certain number of injuries of the genitourinary tract, they were, so far as his experience went, limited. Among a dozen or more bladder and kidney injuries he saw one injury where the kidney had to be resected, but in this instance, as in most others, the kidney injury was only a fraction of the total injuries; the gut, diaphragm, and lung were also injured. Unless one had some data with reference to the end results in these cases, it was foolhardy to draw conclusions, and there was no way as yet to know the ultimate outcome. His immediate mortality at the front was about 4 per cent. Dr. Beer said he did not want his hearers to go away with the idea that the army surgeon spent all his time operating. He had performed forty-eight operations at one session and, of course, when the armies were in action they worked hard, but usually after from ten to fourteen days of active service there would be a respite and when these times came they spent them in sight-seeing. The speaker related some of his sight-seeing experiences, speaking more particularly of a trip to St. Mihiel and Verdun and of the advantages of Southern France as a pleasure resort, which, he said, the French had not been so ready to exploit as the Germans had been in seeking patronage for their spas. In closing he expressed the conviction that the war was won by our doughboys, who brought into it a new spirit. They were utterly unafraid and had no respect for rifle or machine gun, and by virtue of their wonderful courage they held off the German attacks last June, and subsequently at Château-Thierry they had instilled new courage into the Allied armies, so that there was no question but that to the valor of our boys was due the victory in 1918.

Organization of Venereal, Skin, and Genitourinary Services, A. E. F.—Col. HUGH H. YOUNG of Baltimore delivered this address, in which he related his experiences in France in connection with the work of the Venereal Division of the American Expeditionary Forces. He said that he had had the good fortune to cross on the *Baltic* with General Pershing, whose one idea seemed to be to keep everyone as busy as possible. Those on board spent a good deal of time studying French and attending lectures, and it happened to be his misfortune to be selected to give a lecture on the venereal disease problem. For this lecture he utilized charts showing the wonderful progress made in the army in reducing the incidence of infectious diseases, and among these was a chart showing the reduction of the venereal rate in the home army from 155 per 1,000 per year to eighty-four since the introduction of prophylaxis. From this he drew the deduction that it would be possible to accomplish the same results in the army in France. General Pershing was very much interested in medical problems and soon read up on the venereal problem until he set a pretty rapid pace even for the specialist in this field. General Pershing had had considerable experience with the venereal disease problem on the Mexican border, where the Mexican population was to a large extent infected with syphilis, and thoroughly realized its importance.

Colonel Young said he landed in England to study the situation there and found the English people quite excited over the venereal disease problem. They had the opinion that there was a great increase of venereal disease among the civilian population. Sir William Osler had assisted in organizing a national association for combating venereal disease, which had an extensive program. They were following what the Australians called the "ostrich policy," not facing the problem openly. The Canadians took the lead in adopting American methods and even went a step further. One Canadian captain, who had at one time been a Kentucky preacher, hit upon the ingenious plan of establishing a viséing office where every man had to have his passes viséd. When a man came in for this purpose he was immediately sent in to Colonel Bullock, who gave him a talk on the dangers of incontinence; he did not, however, rely entirely on his talk to protect the man, but sent him away with a prophylactic calomel ointment and 2 per cent. carbolic. It was believed that as a result of this work venereal disease had been greatly reduced among the Canadians. It was said that at one time 25 per cent. of the British army was unfit because of venereal disease. The Australians looked at the problem a little differently than did the Canadians. They not only used prophylactic measures, but distributed sheaths to the soldiers. The New Zealanders were also doing what they could to cope with the problem. They had one woman attached to the Venereal Disease Division who thought that a soldier would be a soldier and that it was best to establish houses of prostitution. A rendezvous was conducted by an organization headed by this woman, which was called the New Zealand Sisterhood, whose members promised not to infect any Allied soldier, and if they did they were removed from the list of honorable members. At the front the British had suffered very severaly from venereal disease. They had fifteen hospitals from fifty to one hundred miles from the front, each having from 3,000 to 3,500 patients. The British had at one time as many as 112,000 evacuated from divisions as a result of venereal disease. They had practically two divisions unfit for military service. Had these two divisions been before Amiens the debacle of 1917 might not have occurred. The British gave those infected with syphilis only six or eight weeks' intensive treatment and sent them back to their battalion; the idea was that after the war something might be done for these men. In France there was not only grave concern in regard to the prevalence of venereal disease in the army, but also among the civilian population, both male and female. Certainly in the war zone no woman, no matter what her position, was above the suspicion of having syphilis. At a conference on this subject attended by sixty-five physicians it was the consensus of opinion that there was a great increase in the incidence of both syphilis and gonorrhea, that syphilis was probably three times as prevalent in some parts of France, probably eight times as prevalent as before the outbreak of the war. The French viewed with concern this spread of venereal disease and organized a venereal disease service as an annex to the army, which was run by military officers with centers in twenty-one cities, particularly in munition centers. In some of these factories they had doctors to examine the men and women and conducted venereal disease clinics, but they did not make much progress by this method because the women would not avail themselves of these clinics because if seen attending such a clinic they would be branded as venereal disease patients. It would perhaps have been better to have had this service in connection with a general medical clinic. At one time it was estimated that there were 200,000 cases of syphilis in the French army and about four times as many cases of gonorrhea. Syphilographers predicted a pandemic of syphilis after the war, when there would be an interchange of the syphilis of the fireside with that of the front. The French in the treatment of syphilis among their soldiers evacuated the men for six or eight weeks for active treatment, after which they were sent back to the front and expected to continue treatment while with their divisions. It was predicted, however, that there would be 95 per cent. of recurrences. Neither the French nor the British adopted prophylaxis or made the victim of venereal disease liable to court martial. After taking this trip of investigation Colonel Young said he was called upon to formulate a plan for the protection of the American armies against venereal disease. General Bradley had cooperated with him and as a result they had developed the work in three categories. First they urged the provision of amusement and the advisability of keeping the men busy as far as possible. They urged the Y. M. C. A. to establish hotels for the soldiers on leave and he had been appointed liaison officer. He urged that prophylactic stations be established in each of these hotels. This idea was at first opposed, but finally adopted, and the authorities of the Y. M. C. A. now recognized that this was one of the broadest minded things they had done in their war work and one of the most effective. The second thing that became evident to them was that something must be done for the French civilian population. At Neufchatel, the center of the training area, there were practically no French physicians. The doctors had gone to the front and many had been killed, so that in many localities one doctor was doing the work that before the war had

been done by six or seven, and in some areas there was no physician at all. It was in such an area that the American forces were to be billeted. To meet these conditions it was proposed to establish a service outside of the army, but conducted by army officers. The Red Cross cooperated with them in this plan to a remarkable extent, and as a result they had a series of routes looked after by a medical officer, who was provided with a Ford motor car and a chauffeur and in this way they were able to cover the country for a radius of twenty to thirty miles about Neufchatel. A little later they organized tent guard hospitals, for they discovered that there were a large number requiring surgical treatment and many cases of contagious disease besides venereal diseases. Scarlet fever, meningitis, and other diseases of childhood, from which our men had been protected by the public health measures in this country, became rampant. They had also hoped in this way to get in touch with the women who had venereal disease, thinking that if these women could be gotten into the hospital they would be removed as sources of infection. A third step in coping with the problem was to introduce into the army the prophylactic measures employed in this country. They felt that the American authorities must adopt more radical measures than the English and French had done. It seemed ridiculous to provide hospital treatment for all cases of venereal disease in the army when no such provision was made in civil life. If cases of venereal disease could be treated as ambulatory in civil life it seemed that they might be so treated in the army; hence they attempted to so simplify the treatment that it could be carried out by the soldier without carrying him back to a hospital. This method also possessed the advantage that the course of treatment could be prolonged and the man given two, three, or four courses of treatment. This method was adopted and the Department of Urology was the first one for which consultants were provided in the first three or four months after our entrance into the war. By August 1, 1917, Captain Boyd organized the work in the First Division and accomplished a great deal. It had been most interesting to watch the development of the work as the doctors learned to understand it. Their work was becoming very complicated when Colonel Keyes came over and saved the day. Together they had studied and planned and found the work always interesting, and they had always had General Pershing's co-operation. It was he who adopted the court martial order, making the contraction of a venereal disease a court martial offense. He felt that this was not doing the men an injustice, for if the prophylaxis was used early there was very slight danger of contracting infection. The charts showed that the failures with the prophylaxis were directly in proportion to the time after exposure at which it was employed, and that the rate of failure was very small if it was used within four hours. They had had a great deal of trouble with the negro troops. The urologists finally put in the order that every negro who left camp had to take the prophylactic treatment on his return. The result was that prophylaxis was not popular among the colored troops. When the earliest troops went over, composed largely of free lances from Boston and New York, they were welcomed by the French women as saviors and they ruined their good venereal disease record made in this country in two or three weeks. Many troops were debarked at the small port of St. Nazaire, where there were no facilities for caring for the men and they stayed there ten or twelve days before they were sent to camps. As a result from 10 to 20 per cent, of the men were infected. When the men got to camp it was very evident that radical measures would have to be adopted, so a report was prepared for General Pershing as a result of which he issued an order keeping all houses of prostitution out of the camp boundaries. The charts showed that after this order went into effect the venereal disease rate fell from 16 per 1,000 per month to 2 per 1,000 per month. Among the Negroes the rate fell from 109 in October, before the order went into effect, to 11 in January, after the regulations were in operation. This order not only had as its object to combat prostitution, both clandestine and otherwise, but it forbade the sale of liquors other than light wines and beer and it made every officer responsible for his men. The venereal rate of his troops was attached to the rate card of every officer and after that the Urological Department was unquestionably on the map. The men next went to the front and it became necessary to organize against venereal diseases in the fighting zone. An early study of the situation showed that practically all the skin diseases were preventable, and this applied especially to scabies and lice, which were the most prevalent of all skin diseases in the army. It was remarkable what could be done to prevent these diseases by proper provisions for cleanliness. It was found that 90 per cent. of the diseases for which men were evacuated was due to lousiness and scabies and that practically 95 per cent. of these were preventable. They had encountered difficulties in getting simple and efficient hot air disinfection and bathing facilities, but after they succeeded in installing suitable apparatus they reduced the rate of these skin affections from 425 to 17 per 1,000. The incidence of lice was reduced from practically 100 per cent. to eight or ten per cent. The French carried their bathing apparatus right up to the front, and practically all of this apparatus used by the Americans was provided by the French. When the Germans were driven back they captured German bathing apparatus and in this way they had been able to keep the American troops pretty clean. They decided not to evacuate the men from the front on account of skin diseases, but to rely upon methalene and powders of that sort. There was for each division one field hospital for the treatment of skin diseases. Every man who came to a bath was examined by the orderly and in this way they got the cases of skin disease early. The venereal disease cases they took back to a work camp where they were treated and made to work. Every man in the army was examined before he was sent home and it could be said that they were the cleanest body of men ever gotten together. When one thought of this he could not help but wonder whether all the money spent on ribbons and decorations for Fifth Avenue as a welcome for the soldiers might not be better spent in cleaning up the red light district. The Manual of Military Urology contained much of the experience of the Allies and our own experience with venereal diseases in the fighting forces and would be found very interesting. As a result of prophylaxis the venereal disease rate in the army had been reduced from 91 to 18 per thousand per year. The ultimate result of this venereal campaign was, Col. Young said, the most difficult and important problem before us at the present time.

Administration of the Urological Department, A. E. F.—Col. EDWARD L. KEYES, Jr., of the Medical Corps of the United States Army, spoke briefly of the advantages of an army experience in broadening the physician's views. Pope had said, "The proper study of mankind is man," but the physician too often saw only women. The war would wake in him a deeper consciousness of the life of others as a consequence of his more intimate relations with his fellows. Before the war it would have been inconceivable that so distinguished a man as had spoken this evening should interest himself in venereal diseases, but since the outbreak of the war this had come to pass and these men had found the problem of venereal disease prevention extremely interesting. Dr. Young had put venereal diseases "on the map" in the A. E. F. Practically every item of the work done in the army was originated by him, and no man had ever before accomplished so much in the prevention of venereal disease in an army in the field as Dr. Young had done. Colonel Keyes said he had always questioned the value of statistics and to an even greater extent he doubted the accuracy of army statistics, and this not because of the lack of probity of the army statistican, but because the statistics of one army were not comparable to those of another, because each army had its own peculiar method of collecting and collating statistics; nevertheless the statistics of our army were quite comparable with themselves, because they were made practically according to the same system. For instance, one was quite safe in comparing the statistics of the United States Army of 1914 and 1918. The figures that Dr. Young had shown in the charts were as accurate as it was possible to make

them. Any inaccuracy that might be there was due to the system and not the dishonesty or lack of efficiency of the individual and to the difficulty of interpreting the figures. The figures showing the comparative rates of venereal diseases among the white and negro troops and those showing the incidence of venereal disease before and after the houses of prostitution were put out of business in Saint Nazaire were perfectly reliable, as were also those showing the drop in the venereal disease rate between November and January, when the order in regard to the prophylactic measures went into effect. A most interesting thing was the reaction of the French people. The French had laid down as the basis of their campaign against venereal disease the idea that every man cohabited very frequently when he got the opportunity. The troops when fighting had no opportunity; the troops near the fighting lines had small opportunity, the troops in the rear had greater opportunities, and the troops on leave had every inducement to the wildest debauch. That was their idea of the scale of possibility of irregular sexual intercourse, which they thought was true of every nation. It was the reaction of the French people that men more or less ran wild and that the best thing to do was to establish houses of prostitution where a medical attendant would insure the cleanliness of the inmates. The American reaction was that the whole problem was a sanitary one and their whole effort was directed to putting the opportunity to contract venereal disease out of the way. The experience at Saint Nazaire showed very conclusively that suppression was better than regulation. There were a number of conferences with the French authorities on this subject and their whole attitude toward the matter was so different from ours that it would probably take them a long time to come to understand our point of view. Col. Young had shown that it was perfectly practicable to put into effect what had formerly been merely a theory and accomplished something entirely new in the history of civilization. He thought Col. Young could flatter himself that he was in the very forefront of the fight for a better civilization in that he had placed before the nations this attitude of America in reference to morality.

War Leprosy in France.—Perrin and Brac state that Marseilles is the city where one would expect to find exotic cases of this affection on account of its geographical and commercial situation. But aside from the imported case this terrain also represents an old focus of native leprosy. Hence it might not always be possible to distinguish at first between the imported and autochthonous forms. Advanced cases with tuberculous or mixed leprosy occurring in men known to have come from leprous foci need not be considered here, for we are concerned chiefly with abortive and nervous types. Many of these exotic subjects passed through Marseilles as a clearing point to be repatriated, and the mildness of the cases was remarkable, the general health being excellent and the symptoms few and slight. This could hardly have been otherwise when the men had been originally recruited as healthy soldiers from the colonial possessions of France. All of the cases described and illustrated appear to have been in negroes and Tonkinese.—*La Presse Médicale.*

Prognostic Significance of the Streptococcus in the Sputum of Influenza Patients.—Lochelongue during the last half of 1918 had occasion to examine many sputa in which the following technique was employed. The first stage had to do with the use of Ziehl's method as preliminary to exclude the possibility of an awakening of latent phthisis. These examinations gave results uniformly negative. Next came a gram stain to exclude other bacteria. In the third place the use of Unna's blue stain gave data of importance as to cytology. The specimens were received without any data of explanation, and the above procedures were carried out as a matter of routine. The records of laboratory finds are often without the accompanying clinical data. The finds in the sputa show in general streptococci in chains. The author wonders if this arrangement in chains is not responsible for or indicative of virulence. The chains are associated with monococci and diplococci, and the greater the virulence of the infection the greater the proportion of chains.—*Le Progrès Médical*

Miscellany.

Raphael Blanchard.—The founder of medical zoology or parasitology in France died suddenly on February 28 last at the age of 62. He was graduated in medicine in 1880 and was first prosector to Charles Robin. At a later period he devoted himself to parasitology, anthropology, and medical history. He was made professor of medical zoology in the University of Paris, established the Museum of Parasitology, and founded a periodical, the *Archives de parasitologie*, in 1898. In 1902 he founded the Colonial Medical Institute. With others he had founded, in 1876, the Zoological Society of France, and in 1889 with Milne-Edwards the International Zoological Congress. In 1878 he published in collaboration with Paul Bert a text-book on zoology although his medical degree was not received until two years later, in 1880.

A Spanish Apostle of Vaccination.—In *El Siglo Medico* for February 15, Dr. Albinaña Sanz, by request, publishes a biography of F. X. Balmis, a Spanish medical man of the eighteenth century, concerning whom books of reference give conflicting information. He was known as physician, surgeon, introducer of Jennerian vaccination, traveler, author, etc. The date and place of his birth have been determined as 1753 in Alicante. His father was Antonio Balmis, a surgeon, and his mother's maiden name was Berenguer. Antonio is mentioned as a master surgeon and phlebotomist. The son studied Latin and philosophy in his native town and obtained his surgical training in the Military Hospital of Alicante, where the surgeons gave lecture courses. In 1775 he entered the army medical service and while stationed at Valencia obtained his surgical degree from the local university. A copy of his diploma is given. Abandoning the army he made three trips to the Americas between 1781 and 1794. In Mexico City he was chief surgeon to the Amor de Dios Hospital, and here he also took a degree as Bachelor of Arts.

Becoming interested in botany, he made a special study of medicinal plants, some of which he brought to Spain, including the agave and begonia. He eventually took his degree as physician in the University of Toledo. Two years had been devoted to the study of chemistry and henceforth he practised as physician. As protagonist of vaccination in Spain he led a very active existence. He also branched out as author and wrote a medical history of Guatemala. He led a Government expedition to the various countries which had been colonized by Spaniards, including the Philippines, in order to popularize vaccination, and did some proselytizing among non-Spanish races. He suffered shipwreck in Peru but returned safely after three years and made his report to the King. He was then appointed Inspector General of Vaccination for Spain and her colonies. During the Napoleonic wars he opposed the Bonapartes and repaired to Mexico in the interests of vaccination. Having returned to Spain he translated Moreau's History of Vaccination. His death took place in Madrid in 1819.

A REVIEW OF THE EVOLUTION OF THORACIC SURGERY WITHIN THE PAST FOURTEEN YEARS.*

BY WILLY MEYER, M.D.,

NEW YORK.

ATTENDING SURGEON TO THE LENOX HILL AND POST-GRADUATE HOSPITALS.

MR. PRESIDENT AND GENTLEMEN:—I am sure the members of the Council of our Association will not consider it a breach of secrecy on my part—the secrecy which usually surrounds the deliberations of such a body—if I say a few words with reference to how it came to pass that I am standing before you to-day.

It was our intention to divide this review, and we had asked Dr. W. S. Halsted of Baltimore and Dr. Henry H. Janeway of New York each to consider one half of it. Unfortunately, the heavy work on the shoulders of these gentlemen did not permit them to accept our proposition. We then communicated with Dr. Samuel Robinson of Santa Barbara, Cal., who, as you know, up to a late date represented thoracic surgery at the Mayo Clinic. Dr. Robinson also was unable to comply with our request. In this dilemma our aggressive president, at the time of the last council meeting, divided the gordian knot and simply—I would almost say—"charged" me, although he was courteous enough to "ask" me, to take over this part of the program. As a council member I could not refuse, and so I stand before you to-day, but without any MS. With all the other work on my hands to be fulfilled, it was simply impossible to prepare notes, and so I must ask you to be satisfied with my extemporaneous efforts.

What I intend to present is a review of the evolution of thoracic surgery within the past fourteen years, or, to word it differently, "a bird's-eye view of the present status of thoracic surgery."

It is a little more than a century ago that a French physician, by the name of Itard, first described what he then, and later the medical world, called "acute pneumothorax." If one side of the thorax is wounded and the pleural cavity is opened, a collapse of the lung on the wounded side is the immediate and inevitable consequence, except previously formed adhesions between pulmonary and costal pleura prevent such a collapse. Now, what is it that happens when the thorax is opened, let us say, *e.g.* by a stab wound in an intercostal space in an affray on the street? Immediately air rushes into the pleural cavity and this normal atmospheric pressure, being greater than the normal pressure within, compresses the lung, for, as you all know, the lung, under physiologic conditions, is kept distended in the thorax by virtue of negative pressure that exists within the chest. Therefore, air rushes into the pleural cavity as soon as it is opened, thus disturbing the physiologic equilibrium. On account of its elasticity the lung contracts to a very small organ around its hilum. Air fills the space formerly occupied by the lung. This condition, with its immediate clinical pathologic consequences, is called "acute pneumothorax." It has been the stumbling block for almost a century to the proper development of the surgery of the chest. I cannot, of course, here go into details and state what will happen in a case of acute pneumothorax. I will merely say that soon after the occurrence of a unilateral acute pneumothorax and its first violent sequelæ with reference to frequency and depth of respiration, dyspnea sets in. This is principally due to the so-called "fluttering (or flapping) of the mediastinum." The latter, and with it the heart and the large blood vessels, are pushed toward the other, unopened, side, with each inspiration, on account of the increased atmospheric pressure over the exposed lung, thus reducing the space of the opposite pleural cavity. With expiration the mediastinum returns to its former position or is pushed further outward. The mechanism prevents proper inspiratory distension and the necessary expiratory collapse of the lung on the healthy side. In other words: besides the total collapse of the lung on the injured side, the normal exchange of the gases, also on the opposite side, is interfered with. Carbonic acid is retained in the blood, and this retention soon produces dyspnea and irritates the circulatory center which, in turn, increases the volume of blood in the collapsed lung. It usually does not last long before the one lung is unable to uphold the necessary function of life. The accumulation of CO_2 with its deleterious effect increases, finally ending in the patient's death.

As said before, it is this danger of an acute pneumothorax that has been the stumbling block in the development of intrathoracic surgery, and nothing else.

True enough, surgeons everywhere went ahead regardless of the risk involved. If you look through the surgical literature you will find any number of intrathoracic operations recorded, particularly resections of the chest wall for tumor, and extirpation of lobes of the lung, carried out successfully, without keeping the lungs properly inflated. But in many of these cases it was the accidental presence of adhesions or bands between the lung surfaces and chest wall that prevented a total collapse of the lung and, therewith, the appearance of the acute pneumothorax with its sequelæ; or the surgeon

*Read before the meeting of the American Association for Thoracic Surgery, Chicago, June 10, 1918.

pulled on and steadied the lung (Mueller), preventing in this way the mediastinal fluttering. Certainly, such operations speak for the courage of the surgeons.

Others, mindful of the imminent danger, made use of apparatus that promised to avoid the acute pneumothorax. Thus Quénu of Paris, in the middle of the '90's of the last century, worked out an apparatus on the lines of a diver's helmet, in which the patient's head was placed together with a sponge saturated with chloroform; and Tuffier of Paris soon after advocated the use of insufflation for the performance of operations requiring the incision of the pleura. They tested their suggestions by animal experiments which one of them at least followed up by operations on the human subject in the hospitals of Paris.

America, too, has a right to be proud of what has been accomplished in this field. I am referring to the pioneer work done by Fell with the O'Dwyer tube, and the apparatus constructed by Matas of New Orleans on the basis of the Fell-O'Dwyer tube, for artificial respiration. In 1898 Parham of New Orleans made use of Matas' apparatus in a resection of the chest wall for tumor, the first recorded thoracic operation under differential pressure in this country. His patient recovered.

However, this and similar cases remained isolated. They were interesting cases, and there it ended. More concerted action resulted when the differential pressure idea was conceived anew by F. Sauerbruch in 1903. He had been charged by his chief, the late Prof. v. Miculicz of Breslau, to find a method which would make work on the thoracic viscera as safe as that in any other cavity of the human body. As you all know, the construction of "Sauerbruch's Negative Chamber" in the following year was the result of this work. Thus, the year 1904 marks the real beginning of thoracic surgery by the transpleural route. The apparatus designed for experimental work consisted of a box with the animal's head outside and the body inside. A cut-out in one of the short sides of the rectangle served for the passage of the neck. The air pressure within was reduced, by machinery, to a degree equaling the normal physiological conditions within the chest. This having been done, transpleural incisions could be made in every intercostal space, right and left, or large flaps of the chest walls be raised: the animal continued to breathe as if nothing had happened. When conditions were reversed and the animal's head was put inside of the box and the body outside and the air pressure within the box was correspondingly increased, the same phenomena were observed. On the basis of the artificial reduction of air pressure within the chamber below the normal atmospheric pressure, 760 mm. mercury, this operative procedure was called "operation under negative pressure"; the reverse, "operation under positive pressure." The method as such was termed "operating under difference in air pressure;" or, briefly, "under differential pressure."

It was but natural that an aggressive and scientific man like the late Prof. v. Mikulicz at once tried to put the method into practical use. It took but a few months before the Breslau Clinic was prepared to operate on human beings within a chamber of about 500 cubic feet contents, constructed of iron and glass. The results were published briefly by Sauerbruch in 1904 and created a stir in the surgical world. Whoever could went to Breslau to see what they were doing there. I may mention that I personally was fortunate enough in 1904 to see Sauerbruch do a resection of the esophagus in a dog in the negative chamber, an account of which I briefly laid down in a paper read before the New York Surgical Society in the same year. Soon the chamber was introduced in many capitals of Europe. At our hospital we thought of importing one, but Sauerbruch himself advised me not to do it, because the chamber, expensive as it was, had not been sufficiently developed. A few years went by.

In 1908, just ten years ago, we assembled here in Chicago for the meeting of the American Medical Association. One of the topics for discussion before the Surgical Section was: "Intrathoracic Surgery." Sauerbruch himself had come over as the guest of the Surgical Section. There were present also Professor Schafer of London, and among others the two pioneers in thoracic surgery from New York, Dr. H. H. Janeway and Dr. Nathan W. Green, the latter our present secretary. I had the honor to open the discussion. It was a day never to be forgotten, as we all stood there on the platform, trying to bring out the advantages of negative and positive pressure.

As you will perhaps remember, at that time there was quite a divergence of opinion as to which of the two methods was the better for the patient. A physiologic society of renown had declared itself in favor of negative pressure, for the simple reason that it was more physiologic. So we in New York decided to try to speedily solve this question that was then agitating the surgical world, by building a chamber, on Sauerbruch's principles, which would allow of a quick change from one pressure to the other, without the necessity of moving patient, instruments, and everything else. Up to that time an operation begun under negative pressure had to be finished under negative pressure, and if it had been commenced under positive pressure, it had to be finished under positive pressure. You must permit me to dwell at some length on this important point because it alone was the guiding star which prompted us to construct the chamber which is now at the Thoracic Pavilion of the Lenox Hill Hospital New York City. The apparatus was built with the help of my brother, Julius Meyer, a consulting engineer, whom I had succeeded in interesting in this subject. It permits of changing the pressure from negative to positive and vice versa with the greatest ease, and without changing the position of the patient. But we never made any experiments on the sick human being. Why not? Because it was soon shown that positive pressure in the sick human being was in its effect equal to negative pressure provided the operation did not last too long, and means were provided for eliminating the effect of the continuous positive pressure on the right ventricle of the heart.

Further developments in methods of differential pressure followed in quick succession at that time. First appeared the so-called "mask method," represented by a very ingenious, but complicated apparatus of Brat and Schmieden, which was soon followed by that excellent device of Tiegel. In both stream of oxygen, supplied by tanks, carries the

anesthetic to the lung. The pressure in the lung is maintained by making the patient expire either against a strong valve (Schmieden) or a water column (Tiegel). The latter author proved that *"one millimeter"* of pressure of pure oxygen is sufficient, after the chest has been opened, to maintain life and avoid the appearance of the symptoms of acute pneumothorax. His apparatus is widely used in European clinics.

Almost in the same year, our honored President, Dr. S. J. Meltzer, came out with the fruit of his work, done in conjunction with ours, his new world-renowned and generally accepted method of intratracheal insufflation.

Standing here before you, at the first gathering of the American Association for Thoracic Surgery, and having the pleasure of seeing Dr. Meltzer preside, I trust I may be permitted to touch upon a personal matter. Dr. Meltzer mentioned in his inaugural address to-day that, in the discussion following his presentation of the matter before the New York Academy of Medicine his views were opposed, in the interest of conservatism in surgery, by three surgeons.

Inasmuch as I was one of the three, I would, in explanation, here state that I had been asked by the then president of the Academy, to participate in a "symposium on thoracic surgery." So I was obliged to write a paper, at the time when we were just erecting the negative chamber at our hospital in the thoracic pavilion then under construction. At that very time it was reported to me that Dr. Meltzer had stated that in his opinion thoracic operations on human beings could be done in a much simpler way than by working in the negative chamber; that a catheter in the trachea and bellows was all that was needed. He, a physiologist who had always done scientific surgical work on animals, certainly found these paraphernalia sufficient. I personally had meanwhile seen and learned to admire the absolutely reliable working of the mechanism of the chamber, without the possibility of doing the slightest harm to the patient. In my remarks on that memorable evening at the New York Academy of Medicine, I therefore tried to impress upon my colleagues the great importance of absolute safety. I stated that no matter what apparatus we might use in thoracic surgery on the usually much run down human being, it must be so constructed that it could not possibly do harm to the patient. I further stated that I would be only too happy to personally use intratracheal insufflation as soon as it was sufficiently perfected to render it safe under all conditions. As outward proof of the sincerity of this statement, we set aside a large space, next to the negative chamber and the positive pressure box in our pavilion, for thoracic operations done with the help of differential pressure apparatus other than the two just mentioned. I made this same explanation to our honored President publicly before, at the Annual Dinner of the American Gastro-Enterological Association in Baltimore, a few years ago, and I wish to bring this out again today, also in the light of a controversy Dr. Meltzer and I had in one of the Medical Journals of New York at that time. I want to lay stress upon the statement that I for my part have never been in opposition, but rather in full accord with his splendid discovery. The fact is that I personally have been among the very first in New York to use intratracheal insufflation in thoracic operations upon the human subject.

As a further method for the production of differential pressure must be mentioned pharyngeal insufflation. It, too, bids fair to occupy an important place in thoracic operations.

Thus we now possess four different useful methods for the purpose of properly maintaining the "physiologic" working of the heart and lungs during our thoracic work, viz., (1) the negative chamber and positive pressure box, (2) the mask apparatus, (3) intratracheal insufflation and (4) pharyngeal insufflation.

But, please bear in mind, that they all mean the application of either negative or positive pressure, nothing else, and, that only the use of the differential pressure method,—no matter what the apparatus—enables the surgeon to work in the thorax with the same equanimity and tranquillity as in the abdomen.

I have purposely dwelt at length—perhaps too much so—on the development and importance of the use of differential air pressure in thoracic operations; for, to my mind, it is on the thorough understanding and general acceptance of this principle that the further evolution of this youngest and last child of operative surgery largely depends. There are still a good many surgeons who claim that differential pressure is absolutely superfluous for this kind of work, that we can open the thorax just as safely as we do the abdomen, without any apparatus. But I say once more what I stated at a previous discussion: take 100 patients, with no matter what kind of intrathoracic disease, and divide the pleura without apparatus,—I mean the "virgin" costal pleura, a pleura that is nowhere adherent to the pulmonary pleura,—and compare the resulting mortality from operation on these 100 patients with that of another 100, in whom differential pressure by means of any one of the four methods just mentioned was used. I am sure there will be a great difference. The surgeons who did not use any apparatus will have a far greater mortality than those who did use apparatus. I, therefore, consider it wrong at this time, when we have at last found the means to overcome the acute pneumothorax—the stumbling block to the safe evolution of thoracic surgery for almost a hundred years,—I say, I consider it wrong, now, to simply dismiss the question of the dangers of the acute pneumothorax and throw overboard, as superfluous, all the work of the last two decades; I consider it wrong for any surgeon to-day to refuse to accord a prominent place to differential pressure—be it with chamber, box, mask apparatus, intratracheal insufflation or pharyngeal insufflation—in the surgery of the chest. I also consider it wrong to draw sweeping conclusions from the experience, gained from the treatment of war-wounds of the chest, where conditions are altogether different than ordinarily. Differential pressure alone has made thoracic work as safe as abdominal work; it gives us the right, in doubtful cases, to advise exploratory thoracotomy with almost the same assurance as we advise abdominal incision.

Then, standing on this safe basis of having accepted unconditionally the necessity of maintaining artificially the physiologic difference in pressure

over the lung, after the chest has been incised, permit me to go with you as briefly as I possibly can, over the present status of the surgery of the various organs within the chest, as our President has charged me to-day.

What do we have to deal with anatomically? The chest wall, the pleura, the diaphragm, the anterior and posterior mediastinum, the latter including the esophagus, the heart with the large blood vessels (aorta and pulmonary artery) the lungs and bronchi.

1. *Chest Wall.*—Naturally, I will not speak of the acute and chronic inflammation of the tissues that make up the chest wall, but I should mention the traumatisms that occur in consequence of accidental fracture of the ribs, including the wounds received in battle. However, as that also refers to the lung in particular, I can deal with it later on.

With reference to the chest wall I will here only mention tumors involving this area. I am sure that a number of the surgeons present here have done resection of the chest wall for this cause, for carcinoma, primary endothelioma and secondary epithelioma, *e.g.* recurrence after extirpation of a cancer of the breast, or for sarcoma, in this locality usually involving a number of ribs and intercostal spaces; in brief, all tumors occurring in the region known as the chest wall. With the help of any of the methods for the establishment of differential pressure, we now safely enter the pleural cavity, make out conditions with the hand introduced, and then cut out a window of any desired size, making sure that we have operated within healthy tissue. If we then close up the wound air-tight by carefully placed sutures, having blown up the lung, or—better still, as I personally insist upon—using drainage in a way which will allow air-tight closure, with the lung distended, and at the same time drain the pleural cavity, we shall see the mortality of this very simple surgical procedure reduced almost to a minimum.

2. *Pleura.*—The only type of pleural disease that interests us here is empyema. Inasmuch as a number of papers on this subject are announced for the afternoon, I will not go into this topic very deeply now, but would like to make a few remarks reflecting my personal views on what I have seen in practice and read in the literature.

The main difficulty in curing empyema promptly, *i.e.* to make the lung expand so that the pulmonary pleura will again come into contact with the costal pleura, has been that the fluid compressing it has been allowed to remain too long before evacuation. Firm adhesions form during this period, bind down the lung in many places, often also, in addition, a much thickened, chronically inflamed pulmonal pleura acts like a tight, broad envelope; not seldom infiltrating intrapulmonary inflammatory foci will further resist the desired expansion of the elastic lung tissue.

To avoid a complicated convalescence in empyema, Dr. Howard Lilienthal of New York has proposed the so-called "major thoracotomy," which opens the thoracic cavity by a long, intercostal incision, straight or curved, with or without division of a number of ribs posteriorly, and at the same time permits investigation of the entire pleural cavity from top to bottom.

The present war has tremendously assisted in the evolution of the treatment of empyema. In all our many cantonment hospitals, in all the hospitals at the front and, not the least, in the war hospitals at home, particularly the Rockefeller War Demonstration Hospital of New York City, this subject has been given much study. We are looking forward with keen interest to the presentation of the subject by representatives of the latter hospital at this afternoon's session. It seems plausible to conclude that, if we take pains to allow the lung to expand as early as possible and, further, take care that all the fluid in the pleural cavity is thoroughly and continuously evacuated, a rapidly increasing number of patients will not only be spared the annoyance of weeks and months of sickness, but will likely be cured in a comparatively short time. If we further employ a gentle procedure for permanent drainage, (Kenyon) which at the same time permits of disinfecting the cavity with Dakin's solution or dichloramine-T, and thereby dissolving or breaking into small pieces the deposited masses of coagulated fibrin, it is to be hoped that we shall have won. (See *Annals of Surgery*, August, 1918, Author, "Postoperative Thoracic Drainage.")

3. *Diaphragm.*—I will not here consider the so-called "diaphragmatic eventration," the condition, when, in consequence of the paralysis of one side of the diaphragm, the contents of the abdomen have risen away up, but the diaphragm as such is complete. I will just say a word on the real cases of diaphragmatic hernia, when stomach with omentum and intestine have entered the thoracic cavity through a real hole, a hernial aperture in the diaphragm.

At the meeting of the American Surgical Association just held in Cincinnati, Dr. Downes of New York read an interesting article on a case of diaphragmatic hernia. The definite diagnosis of the existence of such a condition is naturally our first task. Formerly this was very difficult with the help of the ordinary clinical methods of examination at our disposal. To-day, we can prove the existence of such a hernia beyond the shadow of a doubt. The *x*-rays, and particularly a stereoscopic radiograph have clearly brought it to our eyes. In the case just cited, referring to a boy of nine years, Dr. Le Wald of New York, the radiographist at St. Luke's Hospital, put the boy, with a bismuth meal in his stomach, on his head. Naturally, everything that was first in the abdominal portion of the stomach, passed now into the supra-diaphragmatic section. The large air bubbles seen in the picture of the patient in the erect posture above the diaphragm, became replaced by the bismuth in the reverse posture. Certainly, a splendid demonstration. In this particular case, an abdominal gastroenterostomy cured the patient. This will not be possible in every case of this type. Sometimes a radical operation may be required. The surgeon will then have to add thoracotomy to the abdominal section, loosening the stomach all around and reducing it to its normal position under the guidance of his eyes, with one hand in the thorax, the other in the abdomen. If the rent in the diaphragm cannot be closed by suture, a fascia graft, best of the fascia lata from the thigh, has to be transplanted on it and carefully sutured in place.

In passing I will mention "transthoracic laparotomy," *i.e.* reaching the organs in the vault of

the diaphragm through the thoracic cavity and an incision of the diaphragm. At the present time this route is especially resorted to in cases of acute injury.

I am firmly convinced that in course of time many troubles involving the anatomy of the thorax which now are still within the absolute domain of internal medicine, will gradually become borderland cases. Referring to the diaphragm I would mention persistent singultus, the intractable hiccough, as being amenable to surgical treatment. If in a given case everything that medicine offers has been tried without avail and the patient seems doomed by this reflex spasm, an operation may still bring relief. We know that in persistent hiccough following an abdominal operation, the impulse is carried to the phrenic nerve of the side on which the operation was done. In such a case the phrenic nerve could be exposed at the neck, crushed, but not cut, that is, temporarily put out of commission, a procedure proposed by Henschen of Zürich for the temporary inhibition of the working of the phrenic nerve, in place of the permanent elimination of its action by resection.

4. *Anterior Mediastinum.*—Acute suppurations of the sternum, producing accumulation of pus within the anterior mediastinum have been often attacked before the modern era of thoracic surgery. The sternum was perforated by drill or otherwise and the cavity was drained.

A few words might be said on the surgical treatment of tumors of the anterior mediastinum. Whoever has had a patient with advanced tumor of the anterior mediastinum will agree, that these patients lead a life not worth living. The result of the compression of the superior and inferior vena cava and of important nerve trunks, makes their existence miserable. Formerly very little could be done for these patients. To-day, too, a radical operation is usually out of question. By the time when the patient reaches the surgeon, the tumor which is usually malignant, so completely involves the important structures, that it cannot be dissected out. All that can be done surgically is a decompression of the thorax, same as we perform a decompression of the skull in the case of an inoperable brain tumor. Friedrich proposes making the transverse split of the sternum under differential pressure, from an intercostal space of the one side to that of the other, while Sauerbruch advises going ahead under local anesthesia, if possible, dividing the sternum longitudinally from the jugulum down, and switching off side-ways into the third right interspace. With sharp retractors in place, the two halves can be sufficiently separated to permit of careful investigation. In case of malignancy, the divided sternum will relieve the compression; and subsequent treatment with radium and *x*-rays will perhaps bring better results than if the bone were still complete.

A retrosternal thyroid or a tumor of the thymus which cannot be reached from the neck, can, of course, be removed by this route.

5. *Heart and Large Blood Vessels.*—I should much like to talk at length on the surgery of the heart, aorta and pulmonary artery, but all that is still in part "music of the future." You know of the many successful attempts that have been made in closing wounds of the heart by suture, and extracting foreign bodies, broken needles, bullets, etc. It will forever remain Rehn's great merit to have been among the first to boldly attack the heart and the first to successfully close by suture a stab wound of the heart muscle.

I should further greatly like to speak at length of another bold attack made on basis of animal experimentation by a colleague when he was already of advanced age, Professor Trendelenburg, who tried to ascertain whether it would be possible to still help patients with pulmonary embolism by operation. Certainly, the majority of these unfortunates die within a few hours after the catastrophe has set in. You all know of Trendelenburg's operation,—he exposes pulmonary artery, temporarily compresses it in conjunction with the aorta, by means of an elastic tube, makes a small incision into the vessel and, with a special forceps, extracts the thrombus from the embolized artery. The operation has been done on the human subject quite a number of times abroad. One patient lived four days and then pneumonia took him away. I have no doubt that with the application of differential pressure these operations will lose a great deal of their severity. I have tried the operation on the dog in our experimental work at the Rockefeller Institute, incising the pulmonary artery, entering it with forceps and then closing it by suture, and could show him with the wound healed before the New York Surgical Society. According to Trendelenburg all dogs thus operated upon, died at the Leipzig Clinic experiments. Why? I believe, because they did not use differential pressure. We employed it and the dog recovered. So far I have not performed the operation on the human subject. We can, of course, not do it without the permission of the family and when this has been obtained, it will frequently be too late. To ask such permission *before* the primary operation is not well feasible.

A few words on the treatment of thoracic aneurysm. Much work has been done in this chapter. You know of the most interesting experiments of compressing the vessel with metallic bands or with strips of fascia as proposed by William S. Halsted of Baltimore. To-day the operation of choice is "wiring" of the aneurysm. William T. Lusk of New York, has given this operation quite some study and has greatly improved its details. He exhibited a good deal of patience and perseverance in finding a comparatively safe method of introducing many feet of carefully prepared wire of a special alloy into these sacs. The wire will touch the aneurysmatic wall in many places. With the help of electrolysis an eschar is then produced at the place of contact, which invites a deposit of fibrin over the inner surface of the sac, strengthening its wall. With this method some remarkable results have been obtained. One of Lusk's patients, a workingman, returned to his work of cutting stones, another one could carry heavy weights on his shoulders. One of my patients who had been bed-ridden for months, coughing blood, and whom others considered a consumptive, was again able to climb four or five flights of stairs for many months.

Wiring does not mean a real cure, inasmuch as in almost 100 per cent. of the cases the trouble is dependent on a syphylitic infection. The latter needs most careful additional treatment. Particular care, it seems, must be taken with the use of larger doses of salvarsan. Gummatous deposits in

the wall of the sac have been repeatedly observed; if too rapidly absorbed, they, in turn, may give rise to perforation. I have personally seen this in an early case of this type.

The treatment of some type of valvular disease of the heart, by operation too, is still "music of the future"; but it will eventually come under the surgeon's care in special cases. Carrel, with his wonderful experimental work and the late Jeger of Breslau have begun to pave the way in this direction. It is not utopian, to imagine that the surgeon's knife may in the future in some way or other reach the place of the trouble and bring help, *e.g.* in a case of stenosis of the bicuspis or tricuspis, and that thus also this type of heart disease may some day become borderland. The treatment of almost every disease within the chest will likely become borderland in course of time. For almost all the specialties join hands in the chest.

In conjunction with this last statement I would venture here to answer a question of our honored President in passing, which he once put to me in private. He asked: Why call this Association "The American Association for Thoracic Surgery?" It should at least be called "The American Association for Thoracic Medicine and Surgery." I answered that the thorax had been the domain of the internists as long as medicine exists. Thoracic surgery could not come forward on account of the acute pneumothorax, that stumbling block. Now, at last, also this cavity of the body had been safely opened to surgery. Real advance to cure many affections, hitherto inaccessible, could now be made. We surgeons wanted the internists, the anatomists and physiologists, we wanted the specialists for tuberculosis, for laryngology, the neurologists, we wanted, in fact, almost every specialty to join hands with us in the thorax. Therefore, I would plead: Let us continue to call this young gathering of mutually interested colleagues "The American Association for Thoracic Surgery."

But I must leave the heart and large blood vessels, much as I should like to talk further on the subject and its future possibilities,—and pass over to

The Posterior Mediastinum. This being correlated with the surgery of the œsophagus, I will discuss this subject later in connection with the œsophagus and first turn to

6. *The Lungs and Bronchi.*—To discuss fully the present status of bronchial and lung surgery would take several hours. With the limited time at my disposal, I shall be able to only briefly touch upon the subject.

The treatment of *acute* inflammation of the lung, pneumonia, will probably forever remain in the hands of the internist. Still, significant onslaughts have been made to get other specialties to assist him in his big task. I think here not only of serology; I would mention our President's personal work, his artificial production of pneumonia in dogs, and his hope of perhaps finding a way to help these patients with intratracheal insufflation, I would further mention the desire of one of our foremost bronchoscopists of New York, once expressed to me in private, when I had to operate on a very sad case of early bronchiectasis, following tonsillectomy, in a young lady. He wished to have the chance, in such a case, as soon as sign of pneumonia appeared, to introduce the bronchoscope and try, by means of suction or otherwise, to help these patients. I am mentioning these points merely to show how the specialists join hands when it comes to the treatment of the organs within the thorax. But up to date, acute pneumonia, in the early stages, with or without pleurisy, belongs to the internist.

Still, there is one type of acute inflammation of the lung that clearly belongs to the surgeon, and that is acute septic embolic pneumonia; when suddenly in a patient, who, for example, had been subject to frequent attacks of phlebitis of the leg, due to varicose veins, a small infected thrombus is loosened and driven into the pulmonary artery as an embolus, usually into the central portion of the same. These patients are immediately deathly sick, temperature 105-106°, rapid pulse, general malaise, etc. The very high polynuclear blood count will show the beginning gangrene. In former years, these patients were left without treatment and frequently they died. To-day, as soon as the diagnosis has been made on basis of the history, clinical examination, the *x*-ray and other methods at our disposal, it is our duty to suggest to the patient if he is well enough, otherwise to his family, that he permit us to cut down upon the lung to palpate it and, with a special stitch, to attach the infiltrated region to the chest wall, if there be no adhesions, and incise the focus either at the same sitting, or a few days later at a second stage. This type of pneumonia belongs to surgery.

Let me in passing say that the diagnosis of pathologic conditions within the chest has tremendously advanced in the course of the last years, and this is attributable principally to the advent of the stereoscopic *x*-ray pictures, as also to peroral endoscopic methods of examination.

In the discussion of *chronic* inflammations I shall omit that of syphilis of the lung. The disease, of course, exists, and if diagnosed, must first be treated by an antisyphilitic régime. I have lately seen such a case in consultation, having been called in to decide the necessity of surgical intervention. We helped the patient by means of persistent antisyphilitic treatment, without operation. After months of severe and tormenting illness, he is now almost well.

I say, omitting syphilis, we now have to consider two large classes of suppurating lung disease; a *non*-specific and a specific one, calling specific here "tuberculous." The non-specific is represented by bronchiectasis, and the specific by tuberculosis.

Whoever has studied the subject of bronchiectasis, will never leave it again. It is so fascinating. I cannot here dwell at length on the diagnosis. All I would say is, that a patient who shows all the symptoms of advanced tuberculosis, cough, sputum, not infrequently mixed with blood, night sweats, fever, clubbed fingers and toes, but in whom tubercle bacilli have never been found, is in over 90 per cent. of the cases a bronchiectatic. The clinical signs often are extremely scarce. Percussion and auscultation yield very meagre results. If one then analyzes the sputum [a 24 hours' collection] the well-known three layers will be found. The *x*-ray will sometimes support the diagnosis; frequently it is of little assistance. But the bronchoscope is of the greatest help in rendering the diagnosis and localizing the source of the suppurative process.

Let me say right here, Mr. President and gentlemen, it is my firm belief that within a few years we shall have in every well-conducted hospital a reliable bronchoscopist and esophagoscopist, or if not every hospital should create this special position, one and the same specialist can serve a number of hospitals. But he must be a man of whom we know that he will not do harm in introducing the instruments, a man who is able to properly interpret what he sees, who, with the proper aspiration and irrigating apparatus, takes care that first all the secretion of the bronchial tree of the affected lung is aspirated, so that he is able to diagnose from which bronchus and from which branch of the bronchus the pus is oozing. He will then be able to tell us whether one or more lobes are affected. We must be sure of him that he does not make a guess, but states what he has definitely seen. Therefore, bronchoscopy is of such vital importance in making a refined diagnosis in suppurating lung disease.

Bronchiectasis is a disease *originally* of the bronchi, secondarily involving the lung tissue, whereas tuberculosis in the majority of cases is *originally* a disease of the pulmonary parenchyma, secondarily involving the bronchi. Let us keep that clearly in mind. A few years ago I was severely criticised by a well-known New York colleague, who was writing on bronchiectasis because I had begun an article of mine on this subject with the words: "Bronchiectasis is a disease of the bronchial tree, not of the pulmonary parenchyma." In part he was right in his criticism because I had omitted the word "originally." Let me repeat, therefore, and let us bear in mind, that bronchiectasis is *originally*, that means anatomically, a disease of the bronchial tree. But being an inflammatory process, the pulmonary parenchyma will, of course, always become very soon, often simultaneously similarly involved.

With reference to the etiology, bronchiectasis is frequently consecutive to pneumonia, the latter developing into this unfortunate condition. It is furthermore, often produced by aspiration, of solid bodies as well as of liquids. This aspiration very frequently happens during tonsillectomy. We all have seen these sad cases: a young man or woman, 19-20 years of age, tonsillectomy; blood aspiration; suppurative disease of the lung; death. To-day the men who work in that specialty are in duty bound to use methods which will prevent such a result.

In advanced cases of bronchiectasis cavities are found in the bronchial system and adjacent lung tissue, which make the section cut of the lung appear like a honey comb. Within the walls of these cavities lime salts are frequently deposited. They become hard; the entering bronchus constricts in the sequence of ulcerating processes, and, within, the secretion has the chance to decompose. The formation of real cess pools in the lung is the result. The patients often do not cough up, but in the real sense of the word, on coughing, "vomit" the contents in their lung or lungs, so that the muco-pus runs out of their mouth and nostrils simultaneously. It may be of such foul odor, that institutions are obliged to isolate these cases. I once operated upon a girl of 19 years who had been in solitary confinement for this reason for more than eight months.

But what is to be done? Just a few words. As everywhere else, we can here carry out either conservative or radical surgical teatment. The latter is always operative. Up to a short time ago, it was believed that only operation could bring relief. However, what is to be done if both sides, or all three lobes of the right lung are affected? One year ago a young girl came under my care, sent by a colleague from the Golden Gate, who had had repeated attacks of what seemed to be bronchiectasis, subsequent to tonsillectomy. On her way across the continent she was so sick that her mother thought she would die. The case was carefully analyzed at our hospital. The bronchoscopist, Dr. Yankauer, found the entire right lung diseased. Radical operation, pneumectomy, the extirpation of the entire right lung would have meant a very serious interference in the delicate girl, and the mother wished to try and save the life of her child above everything. We agreed to do what was first, several years ago, tried in France, though in different fashion, later in Germany, viz., to irrigate the bronchial tree with antiseptic solutions, with the patient always in a slight Trendelenburg posture, first under general anesthesia, later on under local anesthesia, making use of a special tube, ingeniously constructed by Dr. Yankauer. The bronchial system of the right lung was systematically irrigated with Lugol's solution of gradually increasing strength. To-day the patient is apparently well, she is back in school, having gained almost 25 pounds.

If a solid body has been aspirated into the bronchial tree, causing suppuration, it becomes the province of the trained bronchoscopist to find and extract it, and therewith, in many instances, arrest and cure the disease. In some cases additional operative treatment is indicated.

Conservative operative treatment in bronchiectasis has been particularly urged by men who "have been in it," men who have seen adverse results following more radical work. One of these was the late Prof. Friedrich of Königsberg, formerly of the University of Marburg, Germany. When he visited us here in 1909, he urged me, not to go ahead too quickly in attempting lobectomy of which I had just then seen such splendid results in the dog. He said: "If you go ahead too radically, you may easily give thoracic surgery on human beings a black eye." With this advice of an experienced man in mind, I faithfully traveled through the entire line of more conservative surgical procedures, excepting artificial pneumothorax, for it was seen by Volhard in an advanced case, that after this had been done faithfully *for years*, with apparent success, the disease appeared unabated when the gas insufflation was discontinued.

Volhard's case was an advanced one. To-day I would certainly advise producing an artifical pneumothorax in the early stage of suppurating lung affection, following the aspiration of blood. Tewksbury's remarkable statistics (*Jour. Am. Med. Ass'n*, Feb. 2, 1918) speak volumes in this direction. In view of the results obtained by him, this method seems to be the operation of choice. Some of his cases may have represented lung abscess in the early stage. So far a definite line of differentiation between lung abscess and bronchiectasis in their incipiency, has not been drawn as far as diagnosis is concerned.

For the surgery of advanced cases of bronchiec-

tasis, I personally have tried pneumotomy, as well as all the conservative operative methods known for carnifying and compressing the lung, such as ligation of branches of the pulmonary artery, followed by thoracoplasty; I have also done a wedge-shaped resection of the lung for the same trouble and performed lobectomy. I have seen cure or improvement in not too far advanced cases by means of more conservative methods, and believe they can be conscientiously practiced in some patients. But in advanced cases there is only one method that can cure, and that is lobectomy. My first attempt with this operation in the human being was made in 1909, in a boy of nine years. When stitching up the crushed bronchus, the patient quite suddenly died, probably as a result of vagus reflex. We have gradually increased our knowledge as to the best way of doing lobectomy in America, particularly through the efforts of Howard Lilienthal of New York and Samuel Robinson of Santa Barbara, Cal., formerly of the Mayo Clinic. We have learned how best to treat the bronchial stump. Very much, naturally, has still to be learned in order to make lobectomy a less dangerous operation. Personally I believe that arranging for a wide access to the lung and amputating the diseased lobe, as we do for example, a kidney in nephrectomy, will probably yield best results. As a matter of necessity, I shall have to skip details in this cursory review.

One word yet about the surgical treatment of advanced pulmonary tuberculosis. Our President, in his inaugural address, has just proposed, "that large intercostal incisions should be made for the treatment of pulmonary tuberculosis. If the procedure does not interfere with the respiration, that is, if it proves that the mediastinum sufficiently protects the respiratory activities of the lung in the opposite cavity, steps should be taken to keep the incision open for a longer period."

I am not ready to discuss his proposition at this moment.

However, if we inject and reinject air instead of nitrogen into the pleural cavity we have, it seems to me, what Dr. Meltzer wants, in part at least. Incisions in the intercostal spaces will, I fear, have the tendency to rapidly contract by granulation. They will further expose the pleural cavity and surface of the lung only to the eventual healing effect of the atmospheric air (oxygen), but not the intrapulmonary foci.

If we can inject and re-inject nitrogen or air into the pleural sac the lung will be and remains compressed and can then reap the benefit of long rest and compression. But what about patients with advanced pulmonary tuberculosis in whom the pulmonary pleura is firmly attached to the costal and there are one or more suppurating cavities in one lung? At the present time these patients will die if a proper operation is not performed. Here again, medicine and surgery to-day join hands. Advanced pulmonary tuberculosis has become a borderland disease. Fruitful work in this connection has been done, principally, by Friedrich, Sauerbruch and Wilms. The result aimed at is most thorough compression with every means we know. The diseased lung can be thoroughly compressed in the following manner: resection of a sufficient number of ribs, tenth to second or to first inclusive, so called "extrathoracic thorocoplasty," if necessary, also sometimes of the inner portion of the clavicle under regional plus local novocaine anesthesia; then by phrenicotomy for paralyzing the respective half of the diaphragm, which latter by the intraabdominal pressure will then gradually ascend 3 to 4 ribs and permanently stay there, finally also by Tuffier's operation which first loosens and then compresses the apex, with a plomb that remains permanently *in situ* (apicolysis). The walls of a round cavity, kept before permanently distended by the pleural adhesions, will thus drop together to one that has the appearance of a narrow slit. Fever and night sweats often disappear, the sputum becomes free from bacilli and greatly reduced in quantity or cease entirely, the lung itself becomes carnified, due to the pronounced connective tissue formation on basis of the chronic hyperemia, dependent on the collapse.

It has been shown that at least two thirds of these otherwise absolutely lost patients can still be improved or cured.

Tumors of the lung are treated just the same as an advanced suppuration. Lobectomy can bring a cure in cases that come to operation early.

7. *Posterior Mediastinum.*—The principal disease that interests us under this heading is cancer of the œsophagus. Lack of time does not permit me to even briefly consider the treatment of acute mediastinitis, foreign bodies in the œsophagus diverticula, cardiospasm, benign cicatrical strictures, etc., etc.

Cancer of the œsophagus is the most benign of all carcinomas in our system. It is more benign than cancer of the colon, at least in so far as its pathologic dignity is concerned. One of the reasons for this is that the greater percentage of these tumors are of the squamous-celled type, the kind of tumor, we so often meet with on the face and otherwise on the surface of the body (epithelioma), and which in the latter location is treated with the greatest benefit by radium, a fact known to you all.

Thoroughly aware that conditions accompanying and arising from the resection of the œsophagus are complicated and still mean a great risk to the patient, every thinking surgeon interested in this chapter was ready and only too happy to have the effect of radium thoroughly tested in these cases. We hailed it with intense satisfaction when such a trustworthy, reliable colleague as Dr. H. H. Janeway took this matter up at the Memorial Hospital, New York, and we were grateful when he consented to give us a preliminary report on the result of his experience at the March meeting of the New York Society for Thoracic Surgery, three months ago. For, it stands to reason that if radium could cure cancer of the œsophagus, we should not have to operate. Dr. Janeway then reported 35 cases thus treated, of which some were much improved, but only one was cured, and in this one a piece for microscopic examination could not be excised, to prove that it really was an epithelioma.

Mr. President and Gentlemen: Although Dr. Janeway's preliminary communication is, of course, not the final answer to this question, it is my personal belief that the treatment of cancer of the œsophagus will revert to operative surgery. If radium cannot cure these cases, surgery must learn to do it, and

we are fully justified in going ahead and trying further, in view of the fact that medicinal treatment has a mortality of 100 per cent. At the present moment the radical operation for cancer of the œsophagus is clearly indicated in suitable cases. What we still lack mostly is the ability to render an early diagnosis. Attempts have been made by colleagues abroad, as also by Crump and Stewart of New York, to establish such an early diagnosis with the help of a special method for *x*-ray examination. Special sounds have also been constructed to find a beginning constriction on retracting the instrument.

But neither of these methods has as yet been entirely successful. Still, I am convinced that with further unremitting efforts the early diagnosis and, therewith, early operation will become a reality. Meanwhile, in these years of trial and observation we have evolved a satisfactory method of operation and of after-treatment. Every operator will agree that the surgery as such, required in these cases, is not extraordinary, nor technically particularly difficult.

To-day, after obtaining a wide access, as furnished by the curved incision (Torek), we expose and resect the tumor in the posterior mediastinum, invert and firmly close the distal end of the œsophagus, then extract the proximal portion and transplant it extrathoracically under the skin of the chest. A rubber tube connects the upper opening of the œsophagus with a watertight gastrostomy-fistula. Through it the patient swallows any kind of food as was proven by Perthes, and as Dr. Torek's brilliant case, the only one on record of a cure after resection of the thoracic portion of the œsophagus, so beautifully shows.

If gastrostomy is done by means of the Beck-Jianu method, that is to say, if, with gastrostomy, an inferior œsophagoplasty is incidentally performed, we may, in special cases, hope to at once reconstruct the entire œsophagus extra-thoracically. Certain it is, that operative surgery can to-day make a new œsophagus. There are prospects for further improvements.

The greatest danger in the operative treatment of cancer of the œsophagus is found in a resection behind the aortic arch, the place where the pneumogastrics and the sympathetic nervous system join hands and send their branches to heart and lungs. This place represents the "Achilles tendon of life." The tumors here are often very firmly attached; frequently they have perforated the thin œsophageal wall and grown diffusely into the posterior mediastinum, involving the vena azygos. This is particularly so after prolonged sounding, done in the attempt at widening the stricture. Such preliminary treatment, which is always absolutely contraindicated from the standpoint of operative surgery, is the worst enemy of the surgeon. It often renders the case inoperable.

Naturally, there are limits to radical operation. We are often confronted with cases which simply are beyond the reach of surgery. But do we ever think of excising a cancer of the pylorus that has grown into the liver and into the pancreas? Thus there are also to be found tumors of the œsophagus which simply cannot be excised. Let us leave these alone. We shall have done our duty if we have ascertained, with the help of exploratory thoracotomy, whether a tumor is operable or not. Certainly those that are situated between the aortic arch and the diaphragm are the most favorable for operation, and those adherent behind the aortic arch, the most unfavorable. I am sure, that, if we get the cases early, many a patient's life will be saved and many more will derive benefit from surgery, provided we make air-tight post-operative thoracic drainage a *conditio sine qua non.* Inasmuch as we are going to continue this question in the afternoon, I shall not dwell on it further now.

What has been said about cancer of the œsophagus, holds good for cancer of the cardia. There are many surgeons who would not touch a patient thus afflicted. But how shall we ever make progress in this chapter of operative surgery, if we do not touch it?

I was greatly pleased to hear our President make a similar remark at the last meeting of the New York Society for Thoracic Surgery, when the present status of the treatment of cancer of the œsophagus was the topic of the evening.

These cases, if left alone, die a most terrible death. Quite a number can be diagnosed at a time when operation can still bring help. The surgeon's hand if introduced into the vault of the diaphragm at the time of the gastrostomy operation will make out mobility, glandular infiltration, etc., in one word, the operability or inoperability of the tumor. We have learned also, how to deal with these cases technically. Already five cases of successful operation for cancer of the cardia are on record. I believe that help could be rendered to a great many more patients if we arranged our abdominal operation for an intended gastrostomy in such a way that the thoracic operation could be added at the same time, and particularly, if we practiced Ach's method of inversion with extraction of the œsophagus, pulling it temporarily out of the mouth, and then reinverting it under the skin, extrathoracically. This would mean a one-stage operation, which seems to be the best for the patient, provided his condition permits it. Often, however, operation in two or three stages will be indicated.

I must close, gentlemen. As our President has said: the outlook for thoracic surgery is wonderful. What particularly is to be emphasized is, that the thorax to-day is not only open to surgery, but that it is "*safely*" open to it. Let us further emphasize the fact that to-day there is not one angle or corner in our entire system that the surgeon's knife cannot reach. The thorax was the last fortress to be attacked, and it has been laid open safely to the surgeon's knife by differential pressure methods.

I am sure that any one who has started work in intrathoracic surgery will never give it up. It is of such engrossing interest. However, in order to be successful, he should provide himself with proper apparatus and practise post-operative safe drainage.

It is to be hoped, that a constantly increasing number of men will enter upon this fascinating work. Many minds working in the same direction will get quicker results, for the benefit of suffering humanity.

700 Madison Avenue.

WHAT SHALL BE DONE WITH THE OPEN CHRONIC SUPPURATIONS OF THE CHEST CAVITY?*

By EMIL G. BECK, M.D.,

CHICAGO, ILL.

IT is evident that during the past year we have met quite a different type of empyema from that which we have been accustomed to see. The cases here reported by the previous speakers usually began with a violent infection of the throat, or measles, a pneumonia which terminated in an accumulation of pus in the pleura. The high mortality which accompanies this type marks the principal difference.

We have in the past regarded drainage of an empyema as of very little danger and could usually promise the patient a speedy recovery. In my experience, at least nineteen out of twenty cases would close with the ordinary method of drainage within two months after the operation. The type with which we deal now not only has a high mortality, but the tendency to spontaneous closure is not as favorable. The paper read by Dr. Stewart shows that even with the best methods employed there was a mortality of twelve out of forty-four cases, and those remaining did not close as readily as we would expect.

In addition to the large number of cases which will persist suppurating after empyema resulting from pneumonia, there will be a vast number from the thousands of gunshot wounds of the chest now produced in the war. I trust that the Carrel-Dakin method of irrigation will minimize the number of these chronic suppurative cases, but even under best conditions there is bound to be a large residue of cases when we consider the enormous number occurring through the war. This is one of the reasons why I have chosen the discussion of this subject at this time.

During the past ten years I have had an exceptional opportunity to see and treat many of these chronic suppurative chest cases. Practically all had been treated previously and in some of them the resection of several ribs and decortication of the lung had been tried, but the suppuration persisted nevertheless.

In order to treat these cases intelligently, we must first study the cause for the persistence of the suppuration. The following causes have been found:

1. The retracted and infiltrated lung tissue cannot expand sufficiently to fill the dead space existing between itself and the rigid chest wall. Nature tries to diminish this space by contracting the chest wall, so that the ribs almost overlap, and in many cases there are no intercostal spaces except at the insertion of the ribs at the spine. The diaphragm very often is drawn up two or three inches in its attempt to obliterate the space. The pleura also thickens and diminishes this space to a certain degree. Nevertheless there often remains a cavity holding two or three hundred cubic centimeters of fluid.

2. The pleura often contains microorganisms which are very difficult to reach by flushing with any antiseptic solution, and thus the secretion of pus continues indefinitely.

*Read at a meeting of the American Association for Thoracic Surgery, held in Chicago, June 10, 1918.

3. At times there are foreign bodies present, such as rubber tubing which has slipped in unknown to the surgeon and remained there, keeping up suppuration.

4. In cases of abscess of the lung, the tendency to non-closure is greater because there is usually a communication with a bronchus, which is very often dilated, and reinfection of the abscess cavity after drainage keeps up the suppuration.

5. These chronic suppurative abscesses are often multiple, and when one or two are opened, the drainage and suppuration persists in many small recesses, and only communicate through the branches of the bronchi.

6. In abscesses due to tuberculosis of the lung, the reason for non-closure is still more apparent when we consider the pathology of the tuberculous lobe.

In some cases, especially those of tuberculous origin, the lung retracts upwards toward the hylus, leaving a space below and to the sides. The various shapes of these cavities can be visualized by introducing some substance which produces a shadow on the *x*-ray plate, preferably the bismuth paste, and then taking a set of stereoroentgenograms. Such roentgenograms will give us a clear picture of the location, size, and depth of these cavities. Studying them, we can judge whether the cavity is anterior or posterior and thus plan our operation and treatment accordingly. To illustrate this, I here present this first patient.

This patient is a man of thirty, was in good health before and became ill about one month ago with an infection of his throat, which was followed by a severe pneumonia. The temperature ran from 103° to 105° for ten days, at the end of which time the left chest was filled with a fluid.

After probatory puncture (pus with numerous streptococci) an inch of the ninth rib was resected posteriorly. A counter opening was made at the same time anteriorly and a large perforated rubber tube was introduced, passing through both openings.

This drainage was kept up for two weeks, the patient improved rapidly, and the pus changed somewhat in character, becoming thicker and more purulent. I then withdrew the tubes and injected the cavity with 300 grams of bismuth paste, a mixture containing 10 per cent. bismuth subnitrate and 90 per cent. vaseline.

A set of stereoroentgenograms was taken, the patient being in a horizontal position. From the single plate we would judge that the entire left chest cavity is filled with the mixture. Viewing, however, this set of roentgenograms (Fig. 1) through the stereoscope, we find this is not the case. We note that the mixture simply gravitated to the posterior surface of the pleural cavity, producing a shadow covering practically the entire left chest. It does not fill the entire depth of the pleural space; the somewhat retracted lung and heart are in front of it. This fact can only be visualized by the stereoscopic roentgenogram and not by the single plate.

Proof of this is seen in another roentgenogram taken in the sitting posture (Fig. 2). In rising the bismuth mixture has gravitated downward and left the upper two-thirds of the cavity empty and thus transparent. The mixture accumulated at the bottom, giving a square shaped-shadow, A. We note, however, that a portion of the mixture has been retained in a pocket in the upper portion of the chest. It evidently ran in front of the lung, near the apex. It gives a distinct outline of another walled-off abscess, with a straight waterline mark on its upper margin, B. Such radiograms as this are essential for a correct diagnosis and greatly facilitate the treatment.

In other cases the pleura obliterates nearly the entire chest cavity and leaves a long sinus leading

into a pocket not larger than a crabapple, and this accounts for the persistence. The injection of bismuth into the sinus will here likewise give a clear picture of the existing condition. In some instances radiograms will show a straight channel

Fig. 1.—Bismuth injection in a case of empyema, the patient being recumbent; the mixture covers nearly the entire posterior pleural space.

from the drainage opening of the chest wall directly into the bronchus, which indicates that the pre-existing abscess cavity has shriveled down to a straight sinus, but has not closed on account of the communication with a bronchus.

If there is a suspicion of a foreign body being the cause of a lung abscess, it is of course absolutely necessary that the foreign body be discovered and localized before any treatment is attempted. Here also the stereoroentgenogram is almost indispensable for the determination of the exact location of the foreign body. I have made an extensive study of this subject and refer the reader to my publication entitled: "The Localization of Foreign Bodies by Means of Stereoroentgenograms," published in the "Stereo Clinic" in 1917.

To determine the presence of a communication between the abscess cavity and a bronchus, the injection of bismuth paste is most dependable, because the patient will cough up the mixture. As soon as the existing cavity has been completely filled, the overflow will penetrate into the bronchus and the patient will get a coughing spell, in which he will eject some of the paste.

A word of caution is here necessary, namely, that the paste should in such a case be injected very slowly and the patient be asked not to inhale during this injection, for he may aspirate some of the mixture into the other side of the lung while it is passing up through the trachea. It may also produce a choking spell if a large amount of the paste is forced into the trachea. The mixture must be liquid for this reason. If you realize that the trachea is several inches long and its lumen not very wide, you will realize that it is very easy to clog up this lumen by a column of thick paste and the patient will be unable to inspire. Since there is very often an accumulation of pus in the abscess cavity, the paste mixture will displace this pus and the patient will cough up a quantity of pus before any paste will appear in the expectoration.

I could illustrate to you a large variety of conditions which have been disclosed by means of these roentgenograms, but lack of space for illustrations forbids. I recommend to you very highly the stereoscopic roentgenograms with the injected cavity or sinus before any treatment is attempted. They have been a most useful adjunct in my armamentarium for the treatment of chronic empyema.

After a satisfactory anatomical diagnosis has been made by means of these radiograms, the next step is to ascertain the character and quantity of the discharge. In some cases it is a green, foul smelling pus, in others a serous semi-purulent fluid resembling dirty dishwater, in others a pinkish or chocolate colored thick pus. The color of the pus depends very often upon the substances which have been used in treatment. Irrigations of permanganate or of silver nitrate especially change the character and color of the secretion.

We invariably take a culture and smear of the pus, and, whenever it seems necessary, we inject one or two guinea pigs with a ten per cent. solution of the pus. In practically all the cases we find the staphylococcus; in addition to this we find the

Fig. 2.—Bismuth injection of empyema; patient in sitting posture, showing the bismuth mixture has gravitated downward (A); part of it, however, was retained in a pocket in the apex (B).

streptococcus in about 20 per cent. of the cases. The tubercle bacillus is rarely found in the secretion, even in the cases in which the empyema is positively of tuberculous origin.

We have observed one remarkable fact in this

connection, namely; that in the cases known to be of tuberculous origin in which tubercle bacilli could not be found in the secretions with repeated examination, we have, after inspecting the cavity with bismuth paste, found the tubercle bacilli within twenty-four hours in very large numbers in each smear preparation, often as many as a hundred in each field. This surprising finding was verified in a great number of cases during the past ten years. The tubercle bacilli, however, differ somewhat in their appearance and staining qualities from those which we usually find in the tuberculous sputum; they are beaded, resembling somewhat a miniature chain of streptococcus, staining also much darker than the tubercle bacillus usually does. The number of these bacilli gradually diminish, and within two or three weeks the secretion will be free from the same.

My explanation for the appearance of these bacilli after the injection is the following: The tubercle bacilli live within the walls of the sinuses or the abscess wall and not in the secretions. It requires some irritating substance to provoke their exit. The injection of a substance like bismuth subnitrate produces a leucocytosis within the walls and by this means the bacilli are carried out in the discharge. I suppose the *modus operandi* consists in a battle between the tubercle bacilli and the leucocytes, resulting in the death of the bacilli and their expulsion in the secretion. Possibly the same action may hold good in the case of other microorganisms, and this would in a degree account for the surprisingly rapid sterilization of large infected cavities. I have as yet no confirmatory laboratory evidence of the above theory, but the theory seems plausible and supported by many clinical corroborations.

Treatment.—When the anatomical, pathological, and bacteriological diagnosis is established, the treatment is very much simplified. In former times we used to irrigate these suppurating empyema cavities with various solutions, such as permanganate of potash, weak iodine, boric acid, and other similar substances, but this practice has been discarded by most hospitals, and during the past few years we have rarely seen this practice carried out. It was supplemented usually by secondary operations. These operations, however, were not always successful, unless they were very extensive, consisting of resection of the entire chest wall and decortication of the lung. The patient as a rule would not consent to this extensive, hazardous procedure unless he was very much inconvenienced by the chronic suppuration, and if the condition was not very annoying he preferred dressing his wound indefinitely.

Ten years ago we introduced into surgery a new method of dealing with this class of cases; namely, the injection of bismuth paste. It is unnecessary here to repeat in detail the advantages and technique of this method. By this time the bismuth method is well known and the results from its employment and its dangers are all well defined. Let it be said that after ten years of trial, in almost all parts of the world, it has retained its place and is employed more extensively now than ever. The reports in the literature indicate that at least four out of five cases of the very old neglected suppurative empyemata or lung abscesses may be cured by this simple procedure. Ochsner, of Chicago, reported to the American Surgical Association on June 4, 1909, fourteen cases of empyema, all of which had been operated on (two by Estlander's operation) with sinuses in all cases persisting nevertheless. He applied the bismuth paste in each of these cases, with the result that twelve cases healed completely and two were still under treatment at the time and very much improved. Others have reported equally good results. In my own series of 110 cases, approximately 80 per cent. were cured by the bismuth injection treatment alone.

Omitting minor details, it will be of benefit to mention some practical points in the technique:

Subsequent to a physical examination, a stereoscopic roentgenogram of the entire chest (plate size 14 x 17) should be taken and then the cavity injected with 10 per cent bismuth-vaseline paste: bismuth subnitrate, 10.0; vaseline, 90.0.*

When the cavity or sinus is completely filled with this mixture, another set of stereoroentgenograms is taken. This set will illustrate the exact size of the cavity and its relation to the ribs and other structures in the chest. Whenever a communication with a bronchus exists, the patient will at once cough up the excess quantity of paste.

The second roentgenogram shows the cavity entirely filled with bismuth, and plainly marks the inner boundary of the cavity formed by the thickened pleura. The sizes and shapes of these cavities vary so much that there are no two cases alike. Sometimes we find a small globular sac communicating with the outer chest wall by a long tortuous channel, and then again we find that there exists merely a long sinus which communicates with a bronchus, without any cavity whatsoever.

The first injection does not always produce healing. It requires at times repeated injections during several months, but whenever the discharge changes from pus to a serous character, the injections should be stopped because healing will usually follow. Only when the discharge continues to be purulent should we consider a more radical surgical procedure.

I have tried to ascertain why some cases respond to the bismuth treatment and why others do not. I have noted that whenever the cavity holds more than 200 grams it will be less likely to heal by bismuth injections. Cases which communicate with the bronchi are also more resistant than simple empyema. Some cases will heal shortly after the injection and remain closed for a year or two and the patient be in good health, often gaining as much as thirty pounds, and then the sinus will reopen. The injections are then to be repeated. Closure usually follows for another year or two, and then another relapse after a long period. The patient often prefers to keep on treatment in this way, not being much inconvenienced and perfectly well in the intervals.

There remains a small number, about one in five cases, which have no tendency whatever to heal under any form of treatment, and these require the most radical surgical procedure.

*In former years I employed a mixture containing 30 per cent. bismuth subnitrate, but found that the above mixture produces equally good results and is not likely to cause symptoms from bismuth absorption.

The methods in vogue in dealing with these refractory cases are known as the Estlander, the Schede operation, or the decortication of the lung. The patient who has to submit to one of these extensive surgical procedures is, of course, in a desperate situation. He is told that the operation causes a high mortality and the surgeon cannot promise him an absolute cure even with this method. Aside from that, the surgeon must warn him of the prospect of a considerable deformity of his chest, whether he be cured or not. I have always hesitated to advise such an extensive procedure, and in the last seven years I have not resorted to any of the above mentioned operations. In such cases I have resorted to the skin sliding operation, described in my previous publication on this subject.

POSTOPERATIVE THORACIC DRAINAGE.*

By WILLY MEYER, M.D.,

NEW YORK.

THIS topic of discussion was placed on the program of this, our first meeting, on account of the great importance of the after-treatment of intrathoracic operations for the further evolution of thoracic surgery. "Exclusive of empyema" was originally added to the title because the treatment of empyema takes a place of its own in thoracic surgery. It was desired to call particular attention in our deliberations here today, not to the treatment of empyema, a question which it was known would be discussed by most able gentlemen, but to the best method of after-treatment of operations that concern organs situated in the thorax, *beyond the pleura*, particularly of operations which reach beyond the "virgin"-pleura, not the infected one. That means, operations on lungs and bronchi, heart and large blood-vessels, diaphragm, and the anterior and posterior mediastinum, inclusive of the esophagus. But, inasmuch as the president has now decided to include empyema in this discussion, I shall venture later on to say a few words on that subject also.

Whoever attacks the thoracic cavity for operative purposes will frequently find reason for drainage on general principles, same as in other parts of the body. He will say to himself: "This case ought to be drained." However, the colleagues who have the greatest experience in thoracic surgery, principal among them Sauerbruch, have again and again emphatically advised against post-operative thoracic drainage. On basis of clinical observations they were convinced that these patients had a much greater chance for recovery with the thorax closed air and watertight, than drained.

We have just heard from Dr. Green what a difference it makes if the thorax is not closed in acute injuries. We shall consider the question of whether or not to drain in cases in which, for instance, on separating the adhesions around a suppurating lung a superficial tear had occurred, or on excising the esophagus the thin friable wall of the latter was injured.

*Remarks in a discussion on this subject at a meeting of the American Association for Thoracic Surgery held in Chicago, June 10, 1918.

In 1904 I saw Sauerbruch do a resection of the esophagus on a dog in his negative chamber at Breslau. The pleura was soiled, but he closed the wound completely without drainage after the lung had been thoroughly distended. The dog developed a septic pleurisy, but pulled through the infection, the resulting empyema having been opened and drained in time. But he there had to deal with a strong, healthy dog. If one has to deal with sick human beings, conditions are generally entirely different. Their thorax must be drained from the start, right after the operation, should they recover.

If we drain without taking special precautions, the result will be a postoperative acute pneumothorax, which has the same great dangers to the patient as an acute pneumothorax which sets in during the operation.

The question then arises, how can we avoid the postoperative pneumothorax if we drain.

Having the differential pressure apparatus at our hospital, I worked out a useful method with its help some six to seven years ago. I will describe it by showing the lantern slides. The method provides for free drainage of the pleural cavity through a special stab in a lower intercostal space, the inevitably following acute postoperative pneumothorax being avoided by retaining the patient under a difference of air pressure from eighteen to twenty hours.

I. The first illustration (see illustrations in *Annals of Surgery*, Vol. 68, p. 156, 1918) shows the after-treatment bed which was specially built for this purpose, and corresponds in height to the cut-out which allows the patient's head to slip into the positive cabinet. The original thoracic incision has been sutured throughout after the free cut had been made in one of the intercostal spaces, two or three ribs lower down, and such kind of drainage put in place as the surgeon considered wise. The rubber tube or tubes were cut through outside, close to the wound, and secured with safety pins. Dressing is applied as usual, and the entire drainage wound with tubes and gauze covered by a large square piece of sterile rubber dam, which was made to adhere to the chest wall by means of freely used zinc ointment.

Immediately after operation the patient was left under differential pressure. One nurse then went with the patient's head inside of the cabinet, while a second one ministered to his needs outside, just as though he were in his bed and under ordinary circumstances in his room or the ward. The difference in pressure was kept up continuously, but inasmuch as we made use of positive pressure—merely for convenience's sake—it was necessary to relieve the right heart at regular intervals by stopping the pressure and making artificial respiration, a procedure which can be easily effected with the apparatus. The collapse of the lung, followed by a thorough distention, is one of our best physical means of supporting the heart's action. Usually, after fifteen to eighteen hours, the pressure was turned off and the patient now observed under ordinary atmospheric conditions. If he remained well, he was removed from the apparatus and wheeled into one of the observation rooms in the Thoracic Pavilion, where he remained for another

twenty to twenty-four hours. If his condition continued satisfactory, he was returned to the ward or to his private room. The method, which has been tested out in quite a number of cases, proved very satisfactory and efficient; but it was cumbersome on account of the necessity of having two special nurses.

II. A second method was introduced not long after by Tiegel, who constructed a special metal tube of flexible material which could be lengthened inside of the chest by adding a piece of rubber tubing. Tiegel's drain carries at its outer end a piece of rubber dam properly fastened, which acts as a valve, allowing the fluid to be discharged from the thorax, but preventing air from entering it. Although I have this apparatus in my possession, I have never used it, but Tiegel states that he has seen satisfactory results with it. It is introduced either at one end of the thorax incision or through a special stab.

III. In looking around for a simplified method of postoperative drainage, I struck on Dr. Kenyon's method employed for empyema in children, as described and illustrated in "Johnson's Operative Therapeusis." By special means a rubber tube is fastened airtight in the small intercostal wound which otherwise is closed by layer sutures tightly around the tube. Precautions are taken to prevent its slipping in or out, and the pleural secretions are drained off by syphonage into a bottle below the bed. After some discussion with Dr. Kenyon, this method was adopted for ordinary thoracic operations in the adult.

It was tried for the first time by me in a case of resection of the esophagus for carcinoma at the Post-Graduate Hospital in 1915. The method proved very satisfactory. Air and fluid were seen bubbling out into the bottle. Inasmuch as the tumor, which was situated behind the aortic arch, had perforated into the posterior mediastinum, ligation of the vena azygos became necessary. The ordeal of the various steps necessary in this operation was too much for the patient's general condition. He survived the operation by but a few hours. However, the method had been tested and found extremely satisfactory. The next suitable case presented thirteen months later, in January, 1917, when a man of thirty-two, suffering from bronchiectasis, needed operation. On incising the chest, a free pleural cavity was encountered and the lung found adherent only in one area near the spine, where the aspirating needle proved the presence of pus. The pleural cavity was drained as before, and closed, and then the lung incised. The abscess was found and the cavity in the lung tamponed. On the second day of the after-treatment a suppurative pleurisy developed; the effusion could be nicely observed as regards quality as well as quantity in the syphonage bottle. The patient pulled through and made a complete recovery.

The third case was one of resection of the chest wall for tumor. Although many successful cases of thoracic wall resection *without* drainage have been reported, in this case drainage was employed, and the patient made one of the smoothest recoveries imaginable. In two exploratory thoracotomies for cancer of the esophagus it also proved successful. In the sixth case, a man suffering from bronchiectasis involving both lobes of the left lung, it was decided to do the operation in two stages. At the first stage it was found that adhesions bound the left lung to the costal pleura from base to apex. The lung was loosened throughout, so that it could collapse, and then the cavity tightly packed with gauze. The thorax was closed by suture and Kenyon's drain put in place. More than 1000 cc. were discharged in the first twenty-four hours and a pretty large amount in the following. On the fourth day the patient, who had difficulty in expectoration, developed an aspiration pneumonia and died. However, here again it was shown how freely, by means of this drainage, exudate within the pleural cavity is discharged, the latter remaining at the same time hermetically closed.

Kenyon's method of drainage, it seems to me, bids fair to greatly improve the results of our thoracic operations, to make them oftener successful than seen heretofore. The pleura is a membrane which is much more sensitive to traumatism than the peritoneum. While the latter forms adhesions, the pleura forms an exudate and usually an infected one. The sooner the contents are drained off from this closed sac, the better for the patient. Therefore drainage should be started immediately after the operation, or rather *during* the operation.

Dr. Kenyon has tried the method in one case of so-called internal injury of the thorax which seemed extremely dangerous. It occurred in a boy whose chest had been crushed. In this case the airtight introduction of the drainage method proved almost like magic. From the moment it was in place the boy began to recover.

And now just one word on the treatment of empyema. I think it may be worth while with the many cases of empyema in our cantonment and war-hospitals, where the patients are under most scientific observation and treatment, to test this method of drainage on a larger series of cases. Under local anesthesia the tube might be easily introduced some time between the fifth and seventh day of the original pneumonitis and the thorax drained. By exchanging the syphonage bottle for another sterile bottle containing Dakin's solution or dichloramine-T, the chest might be filled with any quantity of the antiseptic desired, and as often as required, by simply raising the bottle and then lowering it for syphonage. If the patient were then left resting on his side and gently shaken like a barrel, afterwards moved on his stomach, then on his side and his back, also brought into Fowler's or Trendelenburg's posture, the fluid would be made to come into contact with the entire pleural cavity. Inasmuch as Dakin's solution is able to dissolve the coagulated fibrin, and the dichloramine-T also breaks up this material, it is not impossible that one may perhaps be able to dispense with rib resection, as done heretofore, as well as with the old method of the open treatment of the empyema cavity. Of course, this is a mere suggestion. Should it be found successful in practice, it would greatly help the treatment of these patients on account of the immediate restoration of the physiological function of the lung and allowing the pathological fluid to be drained off at the same time.

700 Madison Avenue.

THE VENEREAL SORE PERIL.*

By A. STRACHSTEIN, M.D.,
NEW YORK.

THE disastrous effects that follow an error in the diagnosis of a genital sore are so appalling that it may not be out of place at this time to call anew for extreme vigilance when confronted with the diagnosis of venereal sores.

In a clinical and statistical study of nearly six hundred genitourinary cases, two years ago, the writer[1] came to the conclusion that the safest rule to be guided by is the following: Every genital sore should be considered as a probable chancre until definitely proved to be otherwise.

Major J. V. Klauder,[2] who has recently reported his findings after critically studying 115 cases of genital sores, practically came to the same conclusion. He stated that "every genital sore should be considered syphilitic until proved otherwise."

The means at our disposal for the early diagnosis of a primary lesion are, as is known, the dark field vision, the Wassermann test, the clinical appearance of the ulcer, and lastly, the period of incubation.

It seems that all errors in the diagnosis are caused principally by the fact that the diagnostician relies almost entirely upon a negative finding of only one of the agencies at our disposal instead of all. Even a negative dark field examination with one negative Wassermann test does not exclude the sore from being a primary lesion. The following cases, briefly enumerated, will illustrate some of the points at issue.

Recently the writer came across a case in which a competent dark field examiner pronounced the sore a simple non-syphilitic ulcer because three examinations failed to show the presence of spirochetes. The patient, however, developed a macular rash three weeks later.

Another patient, who was treated for acute urethritis, had a most innocent, simple-looking, non-indurated sore on the foreskin. No dark field examination was then made. He was, however, advised to have a Wassermann test taken, and this was done once on the fifth week and once on the ninth week after exposure. Both tests were then negative, but he came back at the end of three weeks with a typical luetic macular rash on his body. Another similar gonorrheic had several superficial abrasions on the scrotum and developed a positive Wassermann test six weeks later.

A third patient, several years ago, while being under treatment for gonorrhea, remembered having had some ulcerations on the foreskin which were cured by cauterization. He was not told then of the possibility of the lesion being a syphilitic sore. Although he was in robust health for many years following his infection, he recently called at the clinic complaining of incontinence of urine. Examination revealed incipient tabes dorsalis, with a negative Wassermann of his blood but a three-plus Wassermann of his spinal fluid.

What are the important data to investigate when confronted with the diagnosis of a genital ulcer? The following points enumerated, if carefully and jointly utilized in the diagnosis, would practically eradicate all sources of error:

1. Any genital sore appearing over ten days after exposure is most likely a chancre. This, however, is not reliable if the agencies of infection were more than one during that stipulated time.

2. Chancres may be single or multiple, contrary to many text book writers, who still cling to the old version that a single one is a chancre, and when multiple they are chancroids. In the writer's experience, the appearance of the ulcer is very helpful. The chancre is usually a clear-cut, punched-out ulcer having a clean, healthy, and beefy-looking floor. Induration, when present, is diagnostic, but the chancre may be very superficially situated without any induration whatever. There is a sharp line of demarcation of the edge of the ulcer and the tissues surrounding it show no inflammatory changes. The edge is neither elevated nor serpigenous in contour. These features, of course, may vary when there is a secondary infection. There are a great many instances in which the clinical features are so pronounced that one is justified in making a diagnosis of syphilis rather than call the lesion a simple ulcer because two or three examinations have failed to reveal the presence of *Spirochæta pallida*.

3. A positive finding of the *Spirochæta pallida* in an ulcer makes the diagnosis conclusive; but negative findings, no matter how many times done, do not by any means exclude syphilis.

4. The Wassermann test. This serological test is of particular value in those cases in which the observer has no opportunity to study the lesion in its earlier days; also when in repeated examinations by the dark field vision spirochetes cannot be found. One must, however, bear in mind that this reaction does not appear early. Hence, a negative dark field examination and an immediate negative Wassermann by no means exclude syphilis. In order to exploit the full value of this test the blood should be examined during the sixth, tenth, and fourteenth weeks after exposure to the infection before we can say positively that the patient has a negative Wassermann. These conclusions are based on actual experiences with this test.

In conclusion, the writer wishes to state that with all these means at our disposal to make a correct diagnosis there is no excuse on the part of any one to err in so serious a question.

17 EAST THIRTY-EIGHTH STREET.

*Read before the Eastern Medical Society of New York City on May 9, 1919.

Male Pseudohermaphrodism.—Girou relates the case of a supposed girl who came to operation for left inguinal hernia. The condition proved to be an ectopy of a testis as shown by the result of operation and microscopy. There was a pseudovulva present which would have deceived the average anatomist. The clitoris (in reality penis) was 2 cm. long and a hypospadias extended downward to the meatus. The labia majora and nymphæ were perfect. The vagina was a mere dimple 1 cm. in depth. Another gonad was apparently present on the opposite side in the inguinal ring. The breast was masculine, as was also the voice. The upper lip showed a rudimentary beard. There was nothing to suggest menstruation. The subject was quite indifferent to men and was psychically a female. —*La Presse Médicale.*

Medical and Surgical Lessons of the War.

PATHOLOGY OF EPIDEMIC PNEUMONIA IN CAMPS AND CANTONMENTS IN 1918.

By W. G. MacCALLUM, M.D.,

BALTIMORE,

JOHNS HOPKINS UNIVERSITY.

DURING the year 1918, throughout which great numbers of men were gathered for military purposes in camps, there occurred a phenomenal number of cases of pneumonia not only among the crowded troops but among civilians as well.

In looking back over this period it becomes evident that this pneumonia offering as it did a great variety of forms did not correspond in any of its main features with the lobar pneumonia with which clinicians had been familiar before. Indeed, one receives the impression that lobar pneumonia has appeared rather rarely during this time and that it has been in a sense replaced by the other types. Much study has for years been devoted to lobar pneumonia, and it was well known as a disease beginning without definite predisposing infection or illness of another sort, caused by one of the types of pneumococcus and proceeding through a fairly constant febrile course to recovery often after a sudden crisis or to death. At autopsy we have been accustomed to find a broad area of uniform consolidation occupying one or more lobes or parts of lobes resulting from the even filling up of all the alveoli with a fibrinous exudate rich in leucocytes and red corpuscles. That there is much that is puzzling about the mechanism of the production of this evenly distributed exudate has long been a subject of discussion. It will suffice to say here that the form of pneumococcal pneumonia referred to as lobar pneumonia has such clinical and anatomical characters as to make it possible to outline it sharply as a definite disease. The cases arise in scattered fashion and it is only exceptionally that anything approaching the development of a small epidemic of true lobar pneumonia is described.

Among the many cases studied during the year 1918 there were few which presented the clinical and anatomical features of lobar pneumonia, and these occurred in about the proportion to other disease that might be found in any other year. Their relation to the time of the year and to exposure and chilling seemed to be exactly what it always has been.

But in contrast with this expected occurrence of the usual number of cases of lobar pneumonia, there arose epidemics of pneumonia of very different character which seemed to be the immediate sequelæ of other epidemics of some predisposing disease. It is difficult to say how many of these epidemics there were or how many forms of infection may have acted as predisposing influences, but it is certain that measles and epidemic influenza have been the most important of the latter. The statement is made thus vaguely because it has been maintained, not without evidence, that lesser epidemics of influenza occurred in the early part of the year long before the main and generally recognized outbreak. The majority of observers agree, however, that during the winter of 1917 and the spring of 1918, when there were great epidemics of measles, especially in the Southern camps, pneumonia was caused chiefly by a virulent hemolytic streptococcus. After a lull during the early summer there arose suddenly the great epidemic of influenza which swept through camps and civilian population from east to west, and this was followed by pneumonia caused by secondary bacterial invaders which comprised all types of pneumococcus, *Staphylococcus aureus*, *Streptococcus hæmolyticus*, and the influenza bacillus of Pfeiffer.

It will be the aim of this paper to describe the forms of pneumonia caused by each organism and the modifications which result from the nature of the predisposing disease, the virulence of the bacteria, the resistance of the infected person and other less tangible factors.

It would be a relatively simple matter to describe the changes which arise in the course of a pneumonia produced by a single organism, but it must be remembered that in most of the cases several kinds of bacteria were found in the lungs. This is especially true of the cases which followed influenza. One might speak of the first bacteria to gain a foothold after the preliminary disease had become well established as secondary invaders, the next as tertiary invaders, and so on. This is on the assumption that measles and influenza are not bacterial diseases, an assumption which we may safely continue to hold until such time as some one shall succeed in proving their bacterial nature. It appears that in each case one of these bacteria assumes a predominant rôle and multiplies far more rapidly than the others, and it is perhaps reasonable to suppose that it is this predominant organism which produces the inflammatory reaction and stamps the pneumonia with characters which are peculiar to its effects. But it is probable that another organism may then add features which it alone can produce or even entirely cover up with new changes the lesions produced by the first. Thus it is perhaps possible that when the predominant organism in the lung is a penumococcus, the influenza bacillus may be present in the bronchi and cause some alteration in their walls, or that after changes in the framework of the lung have been excited by the influenza bacillus, the hemolytic streptococcus in vast numbers may spread through the whole area causing necrosis of the lung substance and a hemorrhagic exudate.

Our own studies were begun in February, 1918, in San Antonio, Texas, where we found many wards of the hospital at Fort Sam Houston filled with cases of measles. Measles had been very prevalent and there was no doubt in the minds of clinicians that the pneumonia which was proving so fatal was in a great many cases the direct sequel. Other cases did appear, it is true, in considerable numbers, with no history of measles nor of any other predisposing disease but with a story of exposure or chilling or even without that, the illness beginning with headache or nausea, cough, and epistaxis often with pains in the chest or abdomen. But that measles played a great part was most evident to anyone who spent any time in the wards where the

measles patients were collected. The onset of the pulmonary symptoms was awaited in each case with anxiety.

The sputum or smears from the throat in many of these patients showed the presence of the hemolytic streptococcus often associated with the influenza bacillus, staphylococcus, and pneumococcus. We soon came to regard the streptococcus with especial apprehension, however, for it became evident that those who harbored that organism were particularly likely to develop pneumonia. At that time the influenza bacillus was not looked upon as being of such serious import. I was ill myself for two days and my throat gave pure cultures of the influenza bacillus of which I heard with relief. Such was our very proper respect for the streptococcus that we advocated strongly the separation of those patients with measles who harbored this organism in their throats from the rest of the measles cases, being convinced that when they were housed together in a crowded ward it was a matter of only a short time before all became similarly infected so that the proportion of cases of pneumonia was greatly increased. We felt that if we could separate the clean cases of measles from those who carried and distributed the streptococcus we could save them from pneumonia. Such a separation proved impossible there, but was carried out later by Levy and Alexander with the happiest results.

In describing the conditions at Camp Pike, Opie has also emphasized the fact that the introduction of even one patient infected with the hemolytic streptococcus into a ward in which there are patients suffering from pneumococcus pneumonia will give rise to an increased mortality through the engrafting of the streptococcus upon the original condition. A patient convalescent from infection with pneumococcus of one type may in the same way be infected with a pneumococcus of another type and die.

Later, in the epidemic which occurred at Camp Dodge there was a sudden or explosive appearance of great numbers of cases of pneumonia without the coexistence of any epidemic of measles. The pneumonia was of the same type as that met with in Texas and from every case the hemolytic streptococcus was isolated, if we except a few instances of lobar pneumonia which were due to the pneumococcus. We were impressed with the idea that after long passage through many individuals the organisms thus transmitted from one person to another may have gained in virulence so as to be able to give rise to an epidemic of pneumonia without any predisposing disease. Toward the end of the epidemic a few cases of measles which had been isolated were infected and in these the pneumonia was especially severe and ran a rapid and fatal course.

Thus in Texas, and later in Camp Dodge in Iowa, we studied many cases of peculiar bronchopneumonia in which the predominant, if not the sole infecting organism, was the hemolytic streptococcus. These forms of pneumonia commonly followed or were associated with measles but there were numerous cases in which there was no history of measles. There were, of course, other cases of lobar pneumonia which were due to the pneumococcus and occurred during the epidemic just as they would at ordinary times, and these were sometimes complicated by the super-position of the streptococcal pneumonia.

While the hemolytic streptococcus was isolated from all the cases of the epidemic bronchopneumonia and appeared to be in general the predominant organism, other bacteria were also found in some cases. The influenza bacillus was present in the upper respiratory tract, the trachea and bronchi or even in the lungs in a number of the cases (16 of 49), and in one or two it appeared to be present in such numbers that a considerable part must be ascribed to it in the production of the lesions. Staphylococci, pneumococci, and miscellaneous bacteria were occasionally found in cultures from the lungs but not in great numbers except in the old cases, in some of which there was a great mixture of bacteria.

In the autopsies which we performed in these cases the outstanding feature was the occurrence of a form of bronchopneumonia in which the consolidation was nodular in character or extended along and about the bronchioles so as to present itself upon the cut surface of the lung in the form of branched grey opaque projecting foci surrounded by areas of hemorrhage, edema, and collapse. No single sentence can convey the manifold variety found in this lesion, which was, nevertheless, fundamentally the same throughout, although encountered in various stages and different degrees of intensity. Except in the earliest stages it was always accompanied by an effusion of fluid in the pleural cavities with a rather abundant exudation of fibrin. The most striking character of this form of pneumonia is found in the rapid infiltration of the substance of the lung tissue with wandering cells and the new formation of connective tissue in the bronchial and alveolar walls, the interlobular septa, and pleura, and even in the exudate which is found in the bronchi and adjacent alveoli. It is for this reason that the name interstitial bronchopneumonia has been applied to it.

This peculiar reaction to the presence of the streptococcus might be assumed to be the constant effect of the hemolytic streptococcus upon the human tissue, but it appears that, as in the case of the tubercle bacillus, the tissue may react in several ways to the presence of the same organism. This is shown by the fact that in certain cases in which the lesions of the interstitial bronchopneumonia were well developed there were also patches in which the alveoli of the lung were filled with an exudate of leucocytes arranged in a network of fibrin exactly as in the case of lobar or lobular pneumonia caused by the pneumococcus. Since the bacteria are present in relatively small numbers in the interstitial bronchopneumonia and restricted to the bronchi and lymphatics in the lung, and are present in great numbers in the leucocytic exudate of the lobular pneumonia, it appears that the latter is an evidence of a certain lowering of resistance on the part of the tissues. This becomes far clearer in other cases in which there is no induration of the substance of the lung and no organization of exudate but an extensive confluent lobular pneumonia with much hemorrhage in which the alveoli are filled with a fresh exudate of leucocytes, and streptococci in masses lie everywhere throughout the

lung. It will be seen that these forms are comparable with (a) tuberculosis of the lungs with induration and encapsulation of tubercles, (b) similar tuberculosis with the addition of disseminated foci of caseous and gelatinous pneumonia, and (c) confluent or lobar caseous and gelatinous pneumonia.

To make these relations plainer it will be necessary to describe these three forms in greater detail.

INTERSTITIAL BRONCHOPNEUMONIA.

When death has occurred a few days after the onset of the symptoms, as happens sometimes when a streptococcal infection of the lungs supervenes upon measles, the lungs are found distended with air, the surface smooth and the pleural cavity free of fluid. When the lung is incised, all or most of the bronchi are found to contain a purulent exudate, their walls are distinctly swollen and bordered with a band of hemorrhage. The larger bronchi and the trachea are deeply reddened. Microscopically such a lung shows in the bronchi an accumulation of leucocytes with streptococci; the walls of the bronchus are infiltrated with mononuclear cells and so are those of the immediately adjacent alveoli. These alveoli contain a few leucocytes and much blood, but rarely any streptococci. At a slightly later stage the epithelium of the bronchus is often found to be necrotic and merged in a coagulum or false membrane, the wall distinctly thickened by the edema and infiltration with mononuclear wandering cells, the alveoli for a greater distance filled with rather dense fibrin, desquamated epithelial cells, blood corpuscles, and mononuclear cells. Such peribronchial areas are bordered as a rule by edema and collapse of the lung tissue.

If the process has lasted much more than a week the changes found at autopsy are far more advanced. Fluid is found to have accumulated in one or both of the pleural cavities often in very great amount. This is a thin, watery, turbid fluid with a greenish brown sediment and floating shreds of fibrin. Streptococci are present in enormous numbers. The pleural surfaces are covered with a shaggy fibrinous exudate which may be rubbed off, revealing a red velvety granulation tissue underneath. The lung, when surrounded by such a collection of fluid is collapsed, airless, flabby, and dark blue but contains palpable firm nodules of consolidation or even larger dense patches, especially in the lower and posterior portions. Much of it can, however, be distended with air forced into the main bronchus.

When incised it is found that the bronchi as before are filled with a muddy brownish purulent exudate rich in streptococci. The cut surface of the lung is studded with nodules which project above the surrounding lung. These are most often about pea size but they may be much larger and sometimes become confluent. Nearly always there is about them a wide zone of hemorrhage and outside this an area of viscid edema. Closer examination shows a cross section of a bronchiole in the center of the nodule or there is a group of nodules which are seen to surround the terminal branches of a bronchiole. Indeed if the bronchus chances to be cut longitudinally it is found that the firm tissue corresponds with a dense mantle which accompanies it and is composed of the greatly thickened bronchial wall with the surrounding consolidated tissue.

One may see in the center the yellowish or brownish pus, then the thick grey wall of the bronchus itself merging into a rather more yellow border of densely consolidated tissue on each side. Outside this are the zones of hemorrhage and edema. The lobules are marked out sharply in many instances by the very conspicuous thickened interlobular septa which sometimes stand up like grey walls dividing the cut surface into polygonal fields in each of which there are several solid nodules. The lymphatics which belong to these septa are often very greatly dilated and because they are filled with thrombi rich in leucocytes appear as broad white beaded channels almost as large as the bronchioles and occasionally much larger.

This is the usual gross appearance of the streptococcal interstitial bronchopneumonia and microscopically there is found a great exaggeration of what has already been described for the earlier stages. The walls of the bronchi are very greatly thickened chiefly by infiltration with wandering mononuclear cells but also by the formation of a great deal of new connective tissue and a great increase in the vascularisation. The wall which has generally lost its epithelium looks like a dense granulation tissue almost solidly packed with cells which have the general character of lymphoid or plasma cells. The adjoining alveoli are bounded by walls which are enormously thickened by the same process. As one passes away from the bronchus this thickening of the alveolar walls diminishes, to reappear as the interlobular septa or large blood vessels are approached. The alveoli contain dense solid plugs of fibrin with relatively few wandering cells and red corpuscles but numbers of desquamated epithelial cells. Organization of this exudate and of that in the bronchi is frequent. Further away from the bronchi red corpuscles tend to fill the alveoli and there is much fluid.

The interlobular septa are greatly widened by the spreading apart of their tissue by fluid, fibrin, and mononuclear wandering cells. Lymphatics which run in this and in the walls of bronchi and blood-vessels are distended with thrombi which are composed of a network of fibrin without special arrangement, loaded with leucocytes and mononuclear wandering cells. These extend, of course, to the pleura and are almost everywhere plugged and occluded by the thrombi. The pleura, like the interlobular septa, is greatly thickened chiefly by the growth of a layer of granulation tissue with abundant blood vessels springing up into the overlying fibrin.

Streptococci are abundant in the bronchi, in the thrombosed lymphatics, and on the surface of the fibrin which overlies the granulation tissue of the pleura, but they are not to be found in the alveoli or anywhere else in the lung. This appears to be a matter of much importance as may appear later. It is thought that from the bronchi they extend by a process of growth through the obstructed lymphatics to the pleura.

Other cases in which in all parts of the lung these lesions of interstitial bronchopneumonia are predominant and conspicuous may, however, present a few patches of a compact grey consolidation of the lung tissue which differs in appearance from the

more familiar peribronchial nodules. These patches are found to be areas in which the relatively unchanged alveoli are filled with an exudate of polymorphonuclear leucocytes with a network of fibrin. They differ from the other areas not only in that the alveoli are filled with leucocytes instead of epithelial and mononuclear wandering cells but especially in the presence in this intra alveolar exudate of great numbers of streptococci. This is regarded as the combination with interstitial bronchopneumonia of areas of lobular pneumonia which because they contain a luxuriant growth of streptococci seem to present the effect of a lowering of resistance.

This lowering of resistance of the host to the invading organisms goes further, however, in other cases in which there is no restriction in the multiplication and invasion of the bacteria. Instead of being imprisoned in the bronchi and carried to the pleura only by migration along the lymphatics, the whole alveolar substance of the lung is full of them. There is no barricading growth of connective tissue, no filling of the alveoli with dense plugs of fibrin which quickly become organized and strengthen the barricade, but instead without any thickening of alveolar walls, interlobular septa or pleura, the alveoli throughout great areas are filled with an exudate of leucocytes and blood in which tangled masses of streptococci thrive and soon bring about widespread necrosis not only of the cells of the exudate but of the tissue itself. This is a confluent lobular streptococcal pneumonia and appears to correspond with the lowest resistance in the invaded host. It is in a sense comparable with what is found in the lobar pneumonia caused by the pneumococcus but is, of course, different in detail and lacks the uniform sudden spread of the process in lobar pneumonia.

In all these cases, but especially in the more acute forms, the infection of the trachea, larynx, and nasopharynx is very intense; streptococci and many other kinds of bacteria are found in quantities strewn along the surface of the mucosa. The tissue itself is very hyperemic, rather swollen, and infiltrated with leucocytes and mononuclear cells. In many instances it was noted that the voice became toneless and husky and finally all voice sounds were lost so that the patient could speak only in a hoarse whisper or with the most violent efforts bring forth an audible sound. This aphonia seemed especially common in the severe cases which followed measles. At autopsy the trachea and larynx were deeply reddened in those cases and the tracheal mucosa was often covered with little flecks of bran-like exudate and superficially ulcerated in places. Similar ulcers of a much greater size and covered at times with a greenish pseudomembrane were found on the pillars of the fauces, the edges and base of the epiglottis, the aryteno-epiglottic folds, the mucosa of the pyriform sinuses, or within the larynx. They were especially common upon the vocal cords and in the cases of aphonia were found to have eroded deeply both cords from end to end. Occasionally the streptococci which are abundant in these ulcers extend into the substance of the larynx wall causing a deep phlegmonous infiltration in those tissues.

The tonsils were not especially inflamed, and although the crypts occasionally contained masses of organisms including streptococci there was nothing to suggest that they had been primarily infected.

Mention has been made of the regularity with which there occurred an abundant effusion of fluid into the pleural cavities about the affected lungs and of the rapidity with which the pleura became thickened by the formation of granulation tissue. This accumulation of fluid which soon assumed a purulent character became the especial concern of the surgeons who devised various methods of treatment. There was for a time much discussion as to whether it were better to aspirate the fluid or to lay open the thoracic cavity either by an incision between the ribs or by the excision of a portion of a rib. There were advocates of both methods, since it seemed that the great object must be to remove the infected fluid as thoroughly and as quickly as possible. Difficulty was experienced in accomplishing this in some cases because of the fact that some of the exudate had become encapsulated or imprisoned between adjacent surfaces within the pleural cavity by adhesions. Even though these encapsulated pockets, which might lie anywhere but were very often found between the mesial surface of the lung and the pericardium, could be evacuated the result was often unfavorable, the patients became cyanotic and died in a sort of shock. In many other cases they died many days after the operation, usually with abscesses in the lung and with complications produced by the infection of other organs. The Empyema Commission, which worked at Camp Lee, concluded that the rapid death after the establishment of an open pneumothorax was chiefly the result of asphyxia due to the complete collapse of the lung on that side and the partial compression of the opposite one, which in a man whose lungs were already largely occluded by pneumonic exudate was too great a burden. They decided to risk the danger of the presence of the infected fluid and to operate only in a late stage when adhesions had fixed the lung to the chest wall and thereby made it difficult for the mediastinal tissue to bulge over into the opposite side when the pleura was opened. The results were greatly improved by this delay. Later, Major Evarts Graham and Captain Bell worked out this matter experimentally and found that a great effort is required to maintain adequate distension of the lung and aeration of blood when the opening is made in the chest and that the yielding of the mediastinal tissues is such that the opposite lung is also greatly embarrassed since so much of the negative pressure ordinarily exerted on it by the chest is responded to by the bulging of the mediastinum. They found that if the opening in the chest bore a certain relation to the size of the orifice of the glottis, respiration might be successfully maintained but that if it surpassed in size these calculable dimensions no effort however violent on the part of the animal could maintain the distension of the lungs and aeration of the blood. When adhesions and thickening of the pleura have been produced, however, the mediastinal tissues are held more rigidly and a very much greater opening can be made with impunity. They thought the presence of the fluid with its bacteria less dangerous.

In the older cases which had survived many days

it was often found that the lung, although completely collapsed showed extremely little indication of having been the seat of a severe pneumonia. On the other hand, many presented quite large abscesses or areas of cheesy necrosis about which the consolidation was dense. These were commonly infected with several kinds of bacteria but sometimes contained streptococci alone. They appeared rather more frequently in the cases in which there was lobular pneumonia but were sometimes found in those in which only the evidences of interstitial bronchopneumonia remained. Many of these abscesses had discharged their contents through the bronchi and there remained in their place cavities with rough necrotic lining.

Occasionally such cavities communicated also with the pleura so that there was a fistulous tract extending from the bronchus to the pleura. In a few cases the bronchi throughout the lung became greatly dilated, but this, in our experience, was not a common occurrence.

The other organs of the body were surprisingly little altered in these cases. In most instances the streptococcus appeared not to invade the circulating blood so that our blood cultures were sterile although whenever there was a combined infection with the pneumococcus the latter organism grew out on blood cultures.

It was rare, therefore, to find endocarditis caused by the streptococcus and equally rare to find infected infarcts in the distant organs. Pericarditis with fibrinopurulent infusion was more often seen. It appears, however, that a few organisms gain the general circulation from time to time, as will be shown by the occurrence of infection with these organisms in certain places in which necrotic tissue and hemorrhage have given rise to a point of lowered resistance suitable to their growth. This is seen in those cases in which degenerative changes in the rectus abdominis muscles are followed by rupture with hemorrhage and localization of the bacteria in the necrotic tissue.

It is difficult to understand the reason for the development of hyaline degenerative changes in the muscle fibers of the rectus muscles but as in typhoid fever they are to be found in various stages in muscles which show no gross alteration whatever. It is only when this degeneration has proceeded to an advanced degree that some slight exertion or an attack of cough causes the muscle to tear across with the extravasation of a quantity of blood which appears as a bluish mass bulging into the peritoneal cavity and retained by the sheath of the rectus.

Microscopically the early stages show single fibers involved with a loss of the cross striations and later the collection of the substance of the fiber into formless clumps of red staining material still enclosed in the loose sarcolemma sheath. Later the nuclei of the sarcolemma seem to sink into the central mass and to multiply greatly so that a gradually disappearing clump of pink stained material is seen to be surrounded by numbers of cells which appear to have arisen from the sarcolemma itself although it is also possible that they may be wandering cells. The intervening connective tissue increases greatly in the number of its cells so that the whole area comes to look like a very cellular granulation tissue, in which, however, one can always distinguish the peculiar elongated groups of sarcolemma nuclei which mark the place of the original fiber. The rupture of the muscle occurs usually in a rather earlier stage and about the mass of blood are found the torn ends of the degenerated fibers. In some instances abscesses are formed in the same symmetrical way in the lower third of each rectus muscle, but the bacteria cultivated from these have proven to be pneumococci.

Another curious phenomenon which accompanied these intense infections with streptococci and pneumococci was recognized only by microscopical study. It was the cessation of spermatogenesis in the testes. Every stage in the degeneration of the epithelium of the tubules could be recognized, beginning with those in which all stages down to the spermatids are found without the formation of actual spermatozoa and ending in those in which, since mitosis is brought to a standstill, nothing remains but the line of spermatogonia and of Sertoli cells. Still more profound changes which result in a complete hyalinization of the whole tubule is also found, but when these are in patches there may be some question as to the part played by some former infection such as mumps or syphilis. Dr. Mills will publish later a detailed report upon these changes.

The description of the pneumonia in this simple fashion may perhaps be regarded as misleading, since the complexities of the bacteriology are well known and have already been mentioned. It is true that cultures from the sputum may show a variety of organisms often including the influenza bacillus and different staphylococci, but this might be expected since sputum passes through the pharynx and mouth in which it readily becomes contaminated. The general predominance of the streptococcus was very marked, however, and it was the only constant factor. Furthermore, its relation to the lesions in sections stained to show all the bacteria in the lung left its rôle indisputable, and this seems after all the only perfectly trustworthy guide as to the significance of an organism. Even so, the influenza bacillus was found in the bronchial exudate in a number of the cases, and it is impossible to say that it may not have played a considerable part in the production of the lesions, especially as in one case the streptococci were very few, so that the Gram negative bacilli held the predominant place. In this case, too, the lesions were strikingly like those which we found later in cases in which the influenza bacillus was present in pure culture.

The pneumococcus in this epidemic was always associated with lobular pneumonia, but it could be overgrown by the streptococcus, and in several cases, although it was cultivated from the circulating blood and persisted in the distant organs and in endocardial vegetations at the autopsy, it could not be cultivated from the lung. Nothing but the hemolytic streptococcus grew there, although the pneumococci were still recognizable in great numbers in the sections.

Once or twice we found such a combination of infections that in the same lung there was lobar pneumonia in one lobe with living pneumococci, and an interstitial bronchopneumonia in the rest of the lung with streptococci. These lesions seem not to have overlapped, and it was remarkable that in the area of lobar pneumonia there was no induration or

infiltration of the framework or pleura, while immediately on passing over into the other area where the streptococcus prevailed the pleura became thickened with a layer of granulation tissue, and the interlobular septa and bronchial walls stood out with unaccustomed prominence as dense walls. In these cases the pneumococcus had circulated in the blood, but no streptococci could be found there until just before death. After death, of course, the heart's blood contained them.

But no matter what the complexities and variations of these cases, they allowed themselves to be analyzed into those caused by the pneumococcus which were lobar pneumonias and those caused by the hemolytic streptococcus, which were of these types, interstitial bronchopneumonia, interstitial bronchopneumonia with patches of lobular pneumonia, and confluent lobular pneumonia, without any change in the framework of the lung. The influenza bacillus was present in a few cases, and may have been the exciting cause in one or two. The streptococcus was present in all cases, and was often in pure culture, as shown by all bacteriological methods and by the study of the bacteria stained in sections, which latter method demonstrated its causal relation to the lesions most convincingly. How measles affected the respiratory tract is not known, but it is certain that it predisposes to the streptococcal pneumonia, and that the lesions are more rapidly developed and more severe in the cases in which it has preceded the pneumonia than in those others which started in its absence.

——o——

The second epidemic began, as every one knows, in the late summer and early autumn, and spread like the most grim pestilence that has ever been described over the whole continent, and indeed over the whole world. Hundreds of thousands died in this country from the pneumonia which followed close upon it, and there seems to be nothing which has far surpassed it in its destructive effect. Of course, the idea which has somehow come into existence in the minds of the laity that it was, in truth, the pneumonic plague such as ravaged Manchuria some years ago, is entirely absurd. It would not have been possible to miss the plague bacillus in cultures from the very first case, nor to have failed to distinguish its peculiar distribution in the lungs when they were studied at autopsy. Far from being a disease so easily studied bacteriologically and pathologically as the pneumonia caused by the plague bacillus, the cause of influenza is still unknown. In spite of the extraordinary opportunity given to all the scientists of the world to study this disease, and in spite of the great amount of work done in striving toward some elucidation of the cause, no credible statement has been made as to the nature of the living virus, as to its mode of transmission, or as to the anatomical lesions that it produces.

It is true that we state confidently that it is transmitted from infected to healthy persons by a spray of droplets exhaled with the breath, and received in the respiratory tract of people who come near, but we have no proof of this, nor of any other method. No one has died of influenza, so far as is definitely known, although the reports from various cities give figures which would indicate in some cases that great numbers died of influenza, smaller numbers of pneumonia, in other cases about the same number of each. Every one who died in the course of the epidemic disease was found, when there was an autopsy performed, to have died of pneumonia. It was for this reason that no one has observed the anatomical lesions produced by the epidemic disease influenza.

It is known, however, that there are many reasons for believing that this disease is not primarily a disease of the respiratory system, but rather a generalized infection. There are cases in which no respiratory symptoms develop, but which throughout show evidence of some general intoxication or infection which causes great depression, aching, and malaise. Others develop intestinal disturbances with diarrhea, which ultimately pass off without any coryza or cough.

In all the cases there was, however, a change in the biological relation to bacterial infection, such as to lower the powers of resistance to a degree scarcely to be paralleled in any other disease. An index of this is found in the usual leucopenia, which persists in spite of the invasion of bacteria and the development of pneumonia.

The pneumonia was due to the secondary invasion of many kinds of bacteria, including especially, however, the various types of pneumococcus, the hemolytic streptococcus, the staphylococci, and the influenza bacillus. Several of these organisms might invade at once or in succession. The influenza bacillus was searched for with great diligence because of its name and its supposed causal relation to the epidemic disease, and it was found in a great number of cases; in some places in every case, less commonly in other places.

There has been much discussion as to its actual significance, and at first many of those who found it so regularly insisted that it was the cause of the epidemic disease influenza, and were intolerant of any one who failed to find it. But recently it has become rather difficult to find a supporter of this view, and nearly every one has come to look upon it as a common and important pathogenic invader of the lungs, but strictly as a secondary bacterial invader responsible for the pneumonia it may be, but not proved to be the cause of the primary epidemic disease. It is known to be a common inhabitant of the throats of normal persons, and might be expected to occur with increased prevalence among people whose resistance was lowered by such a disease as epidemic influenza, just as the pneumococcus and other organisms were found in greater numbers in these throats.

Bloomfield has felt, as we have ourselves, that the epidemic influenza has many points of resemblance to measles, and that the mechanism of predisposition to secondary pneumonia is quite similar, but greatly intensified in its effects. He has observed a characteristic enanthem in the mouth and pharynx, and a less characteristic but very distinct exanthem or rash in many cases, and has based his belief in its relation to the common exanthematic diseases largely upon these facts. He has also noted the fact that as in measles the skin reaction which should follow the von Pirquet test is absent during the height of febrile illness in influenza, but comes out brilliantly as soon as the fever is over.

Our own experience has been chiefly with the anatomical and bacteriological investigation of the forms of pneumonia which accompany and follow influenza, and these we have studied at Camp Lee, in Virginia; at Camp Dix, in New Jersey; and at Johns Hopkins Hospital, in Baltimore. At Camp Lee we worked at the height of the epidemic, at Camp Dix the influenza itself had just ceased, and there remained cases of pneumonia which were consequently in a somewhat later stage. At Baltimore our material for study comprised all the cases dying at the hospital throughout the epidemic.

At Camp Lee and in Baltimore we found in the fresh cases a pneumonia which was sometimes very sharply lobular in its distribution. In many cases the consolidated secondary lobules stood out with extreme distinctness, separated by air-containing or collapsed lobules so as to present a checkerboard appearance over the pleura and even on the cut surface. But in most instances the areas of consolidation were not so limited, but became confluent throughout several lobules, ultimately involving most of a lobe. In these fresh cases the consolidation presented peculiarities which we have all despairingly attempted to recall in words. It was evidently seen in identical form by most of those who studied these cases, and was clearly a very rapidly produced condition, to be found only in those who succumbed after a short illness. There was no effusion of fluid into the pleural cavity, the surfaces were smooth except for patches of opaque bloodstain, like dull red paint, on the surface. The bronchi contained only a brownish, frothy fluid, and their mucosa was pale. The lung was evidently consolidated and airless in part, especially in the posterior and lower portions of its lobes, and on section these areas were found to be swollen, firm and elastic, but smooth, moist, dark red, and elevated above the surrounding surface, into which they sloped off through an edematous zone. No plugs of opaque rigid exudate were to be seen in alveoli or bronchioles. Instead, there were little depressions like pin holes everywhere, filled with a red gelatinous fluid and separated by thick, slightly firmer lines of lung tissue. These proved to be the dilated ductuli alveolares separated by areas of distended alveoli. The whole area oozed bloody viscid fluid and the change has been spoken of as hemorrhagic edema, but it was more than that, although compact plugs of exudate had not yet formed.

Microscopically, the alveoli are found to be filled with the freshest possible delicate network of fibrin entangling red-blood corpuscles, leucocytes, and mononuclear cells many of which are desquamated epithelium. Every cell in this exudate is perfectly preserved, and in the millions of red corpuscles not even a crenated cell appears, so that the exudate must have reached the alveoli a very short time before. The bronchioles and ductuli alveolares are filled with fluid which gives with the fixing fluid only a delicate fibrillar coagulum. The walls of these bronchioles and ductules are overlaid by a curious hyaline material which is not fibrin and which extends down into the mouths of the atria.

It is, therefore, an extremely fresh pneumonia, qualitatively, but not in distribution like the rather hypothetical stage of engorgement which precedes red hepatization in lobar pneumonia. The dilatation of the ductuli alveolares and minute bronchioles with gelatinous fluid is peculiar, and so, too, is the laying down of a hyaline layer over the epithelium of the bronchioles. Scattered through all the exudate, whether in bronchioles or alveoli, are pneumococci, sometimes fairly numerous, sometimes in incalculable numbers, so that every phagocytic cell is loaded with them and there are millions free in the alveoli. In a great many cases there are absolutely no other organisms in the lungs—culture, mouse inoculation smears, and, best of all, careful staining of the sections for bacteria showed this. It is possible to scan these sections for Gram negative and Gram positive bacteria, so that scarcely one Gram negative organism need be missed, and certainly no significant number of influenza bacilli could pass unseen. Everywhere the pneumococci are in intimate relation with the lesions, and are evidently the cause of the pneumonic inflammation.

This may serve as a description of the early stage of a pneumonia caused by the pneumococcus. It is probably the same whether the organism be of Type I or Type IV. Later stages show a further confluence of the consolidated areas, and before very long the appearance of definite opaque and rigid plugs of exudate in the alveoli. Hemorrhage continues to be predominant, however, and at all times it seems that one may discern the spaces of uninvolved lung tissue between the areas of consolidation. Pleural effusion is still absent, although the pleura itself is often fairly packed with bacteria.

The striking feature is the phenomenal multiplication of bacteria in the non-resistant lung, which proceeds so rapidly that in the lack of many phagocytic leucocytes those which do appear are soon filled to their capacity while most of the organisms remain free.

In some instances the hemolytic streptococcus was found to be the predominant organism, appearing in incredible numbers in the lungs and bronchi, and outgrowing all other bacteria which may have been present. Then the gross appearance of the respiratory organs was somewhat different. There was no great pleural effusion, since death occurred too quickly to allow of that, but a thin, bloodstained layer of fibrin covered the surface with patches of brownish opacity, and a small amount of bloody fluid was found in the pleural cavity. The lungs were very voluminous and heavy, and bloodstained fluid ran from the bronchi. The anterior portions were usually air-containing, but the whole posterior part was consolidated. On section the consolidated areas were almost black, uniform in appearance, and moist except where grayish brown patches seemed somewhat dryer and still more opaque. It was difficult to see the outlines of lobules of any of the framework of the lung in such areas. The surface of the consolidated area was rather spongy, without any definite alveolar plugs of exudate. The bronchi were deeply bloodstained.

Microscopically, such a lung shows a loose edematous exudate of fibrin with leucocytes, and a great quantity of red-blood corpuscles in all the alveoli and bronchi, with very numerous streptococci in chains and pairs. Most of these are not inclosed in phagocytes, but lie scattered free in the fluid. They are so extremely numerous that the recogni-

tion of their presence in the tissue of the interlobular septa, lymphatics, etc., seems hardly worth while. They pervade everything, and it is not surprising to find that great areas of the consolidated lung have become completely necrotic. Indeed, it is only in the rather marginal portions that the character of the exudate can be made out clearly, for elsewhere it is all merged into the necrotic mass which includes the whole tissue of the lung. In the alveoli within the necrotic areas the streptococci form a tangled mat or feltwork which fills up most of the space. They have grown there as though in the most favorable culture medium in a thermostat.

Intense inflammatory changes in the bronchi, trachea, larynx, and pharynx, are accompaniments of this pulmonary lesion.

It will be observed that this condition corresponds very well with that which we observed in the first epidemic, and described as confluent lobular pneumonia due to the streptococcal invasion of persons of low resistance. The effect of the extreme lack of resistance following influenza makes the rapidity of the invasion even more striking here.

Such were the cases observed at Camp Lee and in Baltimore. There were cases also in which the *Staphylococcus aureus* appeared to be the predominant organism, and in these it was once associated with the influenza bacillus. This case presented a pneumonia rather like that produced by the pneumococcus as described above, but nothing can be determined from one case, and it is to be hoped that those who have found many cases with predominant staphylococcus infection will study the type of pneumonia produced by it most carefully.

We were surprised to find at Camp Dix cases of a quite different character. There were a few which resembled those described above, but in many cases there was no such edema and hemorrhage throughout the lung as we had found at Camp Lee. Instead, the lungs presented the following appearances:

The pleural cavities contained no fluid, but the pleural surfaces were adherent or covered with a thin layer of fibrin. The bronchi were pale, and exuded a thick, sticky, yellow pus. The lungs were pale, and rather distended with air, but throughout their substance could be felt many shotlike nodules and firm areas of rather larger size. On section the whole cut surface was pale and rather dry, and there projected everywhere firm, yellow nodules with smooth, dense, shiny surface or larger area of similar grayish yellow, firm tissue. In the center of many of the nodules could be seen the lumen of a bronchiole exuding a tiny droplet of pus.

The bronchi, trachea, and larynx were pale, but covered with a sticky mucopurulent exudate. This exudate, whether from the bronchioles in the lung or from the trachea, was rich in influenza bacilli. In two cases these were in pure culture, as shown by bacteriological methods and by the staining of the bacteria in sections of the lung. In several other cases the bacillus of Pfeiffer was the predominant organism, although there were other bacteria in small numbers in the lungs.

In every case studied at Camp Dix the influenza bacillus was found either in the lungs or in the upper respiratory tract or nasal sinuses.

Microscopically, the changes in such a lung reminded one at once of those in the interstitial bronchopneumonia caused in the former epidemic by the hemolytic streptococcus, and it is indeed an interstitial bronchopneumonia.

The bronchiolar walls are greatly thickened by infiltration of mononuclear cells and by an enormous new formation of connective tissue. Leucocytes are abundantly strewn through these walls also, and extend into the walls of the adjacent alveoli.

The bronchi are filled with an exudate of polymorphonuclear leucocytes, many of which are loaded with influenza bacilli, while numerous bacilli lie free in the fluid. The adjacent alveoli contain leucocytes, with some fibrin and epithelial cells, but no conspicuous hemorrhage. Instead, the exudate is rapidly undergoing organization, and the strands of connective tissue add to the density of the nodule. The alveolar walls are very greatly thickened, partly by the leucocytic infiltration referred to above, partly by the inwandering of mononuclear cells and the new formation of connective tissue. The walls of blood vessels, the interlobular septa and the pleura are all moderately thickened in the same way. The change differs from that produced by the streptococcus in several ways. The influenza bacilli are restricted to the bronchi, and do not appear in the alveoli, the lymphatics are quite inconspicuous, and are not found distended with thrombi laden with bacteria, and the pleura is not infected as in the streptococcal pneumonia. The absence of great pleural effusions of fluid makes these cases very different from those caused by the streptococcus. Organization of the exudate is a far more striking feature in the pneumonia caused by the influenza bacillus than in the streptococcal form.

The opinion was expressed that such an interstitial bronchopneumonia, when caused by the streptococcus, represented a rather unsuccessful invasion by that organism stoutly resisted by the forces of the body.

A somewhat more successful invasion would show side by side with the interstitial changes certain patches of alveoli filled with an exudate of leucocytes with very numerous streptococci.

In the cases of interstitial bronchopneumonia caused by the influenza bacillus the bacilli are even more sharply restricted to the bronchi by the dense barricade, so that this may be looked upon as an even better example of a stoutly resisted invasion. But there are some cases in which a few patches of alveoli contain a leucocytic exudate loaded with influenza bacilli. This must represent a distinct local victory on the part of the bacilli. In none of our cases, however, was the resistance of the host so lowered by the epidemic disease influenza as to allow the influenza bacillus to invade easily and to produce a widespread intra-alveolar exudate. If we can trust to our observations, the influenza bacillus is not so virulent an organism as the streptococcus. In any one person with resistance depressed by an attack of influenza, secondary invasion of the streptococcus would produce an extensive hemorrhagic intra-alveolar exudate with millions of bacteria, while secondary invasion of the influenza bacillus would succeed only in causing a bronchitis and peribronchitis with induration of the lung. It must be a great lowering of resistance which allows the influenza bacillus to stir up patches of an intra-

alveolar exudate in which it still thrives. One receives the impression that the lowering of resistance after measles is rather less than after influenza, for after measles most of the streptococcal infections ended in an interstitial bronchopneumonia, but after influenza all of them produced a devastating confluent pneumonia, with hemorrhage and necrosis. Even under these latter conditions the influenza bacillus produces only an interstitial bronchopneumonia. I suppose this must indicate a relatively low virulence for the influenza bacillus as compared with the streptococcus or pneumococcus, and perhaps explains the rarity of influenza bacillus pneumonia under ordinary circumstances and the failure of the influenza bacillus to invade except in the train of some predisposing disease.

To summarize, we may say that in the second epidemic the country was swept by a disease long familiar as epidemic influenza, but still of unknown etiology.

The anatomical changes produced by this disease have not been seen by any one; at least they have not been clearly recognized, but every one has realized that the disease produced an extraordinary depression or lowering of the ordinary powers of resistance so that these persons were intensely predisposed to the invasion of any pathogenic bacteria which happened to prevail in their mouths and throats. Pneumonia, therefore, often followed immediately, and all who died showed the pneumonic changes in their lungs, changes which were exceptionally severe and rapidly fatal, on account of the unparalleled spread of the bacteria in the unresisting tissues.

But the type of pneumonia was different according to the organism which happened to invade, and it was possible to recognize pneumococcal, streptococcal, and staphylococcal forms of confluent lobular pneumonia and to distinguish them from each other and from the interstitial form caused by the influenza bacillus of Pfeiffer.

Stress must be laid upon the epidemic character of the secondary invasion, which made it appear that in one camp nearly every case presented a pneumococcal pneumonia, while in another almost every case was due to the influenza bacillus. It is not surprising that with the one-sided view obtained at first by those who observed these cases in one hospital only, there should have been announced the conviction that the bacillus of Pfeiffer was the cause of the primary disease as well as the pneumonia. But broader experience has shown, it seems, that this prevalence of the influenza bacillus in some camps, as in those of the New England States, represented a local condition. In other places, pneumococci and streptococci were the opportune invaders, and we are still quite ignorant of the cause of the primary disease.

Artificial Lemon Juice.—Huerre gives the analysis of lemon juice as follows: Citric acid, 7.50 c.c.; malic acid, 0.50; saccharose, 0.45; invert sugar, 2.00; potassium citrate, 1.00; calcium citrate, 1.00. In addition there are traces of iron and phosphorus. Water, of course, to make 100 parts. If a synthetic lemon juice cannot be substituted for the natural product it must be because something akin to vitamine is present in the latter.—*La Presse Médicale.*

Military Medical News.

High Praise for Roosevelt Unit.—In a letter to the Board of Trustees of the Roosevelt Hospital, Surgeon General Ireland has expressed his appreciation of the work done by the Clarence Mackay-Roosevelt Hospital unit which went to France in 1917 under the command of Col. Charles H. Peck, M. C., U. S. A. More than 33,000 soldiers passed through the hospital of the unit during its operations in France. The unit was first stationed at Vittel and later transferred to Chaumont and was one of the first two units to function in the Medical Department of the A. E. F. In one day more than 3,000 men were passed through the hospital as a result of which the unit received a citation from General Pershing. Colonel Peck received the Distinguished Service Medal while his second in command Col. Rolfe Floyd won the French Military Medal. During the hard fighting at Chateau-Thierry and in the St. Mihiel salient, the unit was changed from a base to an evacuation hospital, caring for as many as 10,000 patients a month.

Dr. Joseph A. Blake, who had charge of the American Ambulance Hospital at Neuilly, near Paris, and later of a hospital of his own near Ris Orange, under the British Red Cross, and who served as general consultant for the American Army in the Paris region, returned to this country on the *Lorraine* on April 27. Dr. Blake has been decorated with the Cross of the Legion of Honor by the French Government for his services in the war and has received the Medaille d'Honneur de Santé de France.

Deaths in the Service.—Major WILLIAM PETER FAUST, M. C., U. S. Army, of Schenectady, N. Y., a graduate of the New York Homeopathic Medical College, New York City, in 1895, a member of the staffs of Ellis and Mercy Hospitals, Schenectady, surgeon to the American Locomotive Works, and health officer of Schenectady who went across with the Schenectady Base Hospital Unit, and afterwards was assigned to Base Hospital No. 33, died from acute nephritis at his home on March 27, aged 45 years.

Lieut.-Col. FRANCIS JOSEPH DUFFEY, M. C., U. S. Army, of Brooklyn, a graduate of the Long Island College Hospital, in 1896, recently returned from service with the American Expeditionary Forces in France, died suddenly while attending a patient in Manhattan, at the age of 44 years. He was a member of the New York Academy of Medicine, assisting visiting physician to the Post-Graduate Hospital and the Neurological Institute.

Capt. JOHN J. HISLOP, M. C., U. S. Army, of Miner's Mills, Pa., a graduate of Jefferson Medical College, in 1892, on service at Camp Wheeler, until discharged for disability in December last, died of cardio-renal disease at his home, on March 5, aged 53 years.

Capt. SHELDON GUTHRIE EVANS, M. C., U. S. Navy, a graduate of the College of Physicians and Surgeons, Baltimore, in 1890, died in Lankenau Hospital, Philadelphia, on March 10, aged 49 years. He was a member of the Association of Military Surgeons of the United States. His last station was at League Island Navy Yard, Philadelphia.

THE IDIOPATHIC SPLENOMEGALIES OF CHILDHOOD.

WHEN the word "idiopathic" is employed it refers to all cases which the limitations of our knowledge of clinical medicine prevent us from classifying, but with the evolution of the science of medicine their number is decreasing. Any case of splenomegaly the etiology of which is known and confirmed should be placed in its special list. Such, for example, are the tuberculous splenomegalies, even when there is no specific lesion existing in any other viscus, and this likewise applies to the splenomegaly of syphilis. The splenomegalies may be the primary manifestation of an infection the causal agent of which is the bacillus of tuberculosis or the *Spirochæta pallida.*

Two clinical types of splenomegaly in childhood are the only ones to be included in the term idiopathic; the first of these is splenic lymphadenia without leucemia. The onset of the affection is insidious, the patient is pale and weak. There is anorexia with vague abdominal pain, and finally a tumor will be discovered in the left side of the abdomen. Hypertrophy of the spleen is now an accomplished fact and the phase of full development is reached. The digestive disturbances become more accentuated. Blood examination shows a considerable decrease in the number of red cells without any increase of the whites. Soon the lymphatic system becomes involved in the process; the lymphnodes of the neck, groin, axilla, mesentery, and mediastinum become hypertrophied with all the consequent symptoms of compression. Later on, nervous and psychic disturbances ensue, the urine becomes dark in color and hemorrhages are frequent. The patient dies in cachexia and anemia after a lapse of several years. This symptomatology is unquestionably that of a serious form of anemia; but the splenomegaly precedes the blood changes, therefore it is not the consequence. The splenomegaly is the direct cause of the anemia, while blood examination shows numerous changes and deformities of the red cell unknown in essential anemia.

The second form of iodiopathic splenomegaly is the so-called primary form described by Debove and Bruhl. The onset is also insidious with a sensation of weight in the left hypochondrium. It rarely begins suddenly with a visceral paroxysm or with general phenomena, such as asthenia, emaciation, and dyspeptic disturbances. Two principal symptoms occupy the stage, namely, splenomegaly and anemia with all the train of phenomena relating to each. The liver is increased in size, while pleuropulmonary accidents are common. The affection is apyretic and hemorrhages are multiple. Blood examination shows a considerable decrease in the number of red cells as well as in the percentage of hemoglobin. The terminal phase of the process is marked by advanced cachexia, anasarca, nervous disturbances, albuminuria, and hemorrhages. The evolution of the affection occupies from three to four years or even more. In this process the symptomatology might be regarded as that of a high grade anemia, but here also the splenomegaly precedes the anemia. What also differentiates the primary splenomegaly of Debove and Bruhl from splenic lymphadenia without leucemia, is the integrity of the lymphatic system. And lastly, there is also a difference in the blood. Unquestionably there is no increase in the leucocytes, there is a decrease in the percentage of hemoglobin and in the number of red cells, but these have not undergone any visible change.

Thus the question stands today, and it is to be hoped that the mystery surrounding the etiology and pathology of these two processes may be solved in the near future.

THE ONEIROSCOPY OF EPILEPSY.

THE number of epileptics whose affection is clinically detected is considerable, that of unrecognized epilepsy is perhaps greater still. Therefore, every diagnostic means at our disposal should be employed and for this reason the dreams of attack should be recalled. A patient offers certain symptoms that the physician may not dare to classify as indices of epilepsy, but if a careful study of the case be made, dreams of attacks will be discovered in the patient's history and the diagnosis of epilepsy can be unhesitatingly made. This is important, because the affection frequently begins with nocturnal attacks and the case will go untreated until the day comes when vigil crises, casting a light on the diagnosis, expose the subject to serious psychic and physical disorders.

From the viewpoint of the prognosis, the dream of attack is of the utmost import, and it is an acknowledged fact that convulsive epilepsy, when there is a tendency to recovery, passes through the attenuated forms of incomplete crises before completely disappearing. When the disease is in retrogression the attacks again become nocturnal, but so long as the dream of attack is reproduced with its four periods, the epilepsy is not cured because it is still in the phase of complete crises. But as soon as the dream becomes simplified and reduced to the first phases only it may be assumed that the patient is on the road to recovery. Also, from the viewpoint

of the prognosis, there is the question of oneiric and postoneiric psychoses. The dream produces delirium acting either as a psychic trauma or by intermingling its elements with the conceptions of the waking hours in such an intimate way that the patient, incapable of discerning them, falls into a state of mental confusion. This applies particularly to children and elderly subjects. If the reported cases of oneiric psychoses be examined, the characters of epilepsy can be detected in most instances and it can logically be questioned whether these psychoses are not largely epileptic manifestations and in reality the dream plays a part in their etiology. If it is true that the oneiric psychoses are usually transitory and mild in character, it is likewise certain that the fits, by recurrence, may end in producing an incurable state of mental degeneration. Now, if the attack which is hidden behind the dream be detected, a rational treatment can be carried out and the patient cured.

What has been said naturally leads to a reference to the benefit which modern therapeutics may derive from the oneiroscopy of epilepsy. The first indication, since the dream of attack is equivalent to an epileptic manifestation, is to submit the patient to a general treatment. It is also known that the waking aura occasionally passes off unnoticed, while by a careful analysis the images of the dream can be separated. Now, the knowledge of the aura is very useful in many cases from the viewpoint of treatment, because when it is peripheral in origin a circular blister can be applied to the starting point of the aura on a given limb, and the successful results of this treatment are no longer to be doubted.

A few words now as to the forensic aspect of the question under consideration. An epileptic is in some countries irresponsible before the courts of law, but it is often difficult to determine if an individual given over to justice for some delinquency is an epileptic. The way in which the offence has been committed is not always an indication in this respect. The two great characteristics which formerly were regarded as epileptic in nature—unconsciousness and amnesia—have long since been recognized as far too inconstant for forming the basis of a serious diagnosis, at least by the French courts. If, therefore, in these circumstances, an examination as to the individual's dreams be made and it can be recognized that they offer the characters of dreams of attack, the logical conclusion will be that the subject is an epileptic. It clearly remains to find out if the act for which the subject is charged was perpetrated under the direct influence of the neurosis. This task is still a delicate one for the expert, but it will have been facilitated by the knowledge already gained from an analysis of the case-history.

In questions of marriage, life insurance, etc., the detection of dreams of attack is unquestionably of the greatest interest, as in the frequent cases where the diagnosis of epilepsy is doubtful but extremely useful if it can be made with certainty.

TYPHUS FEVER.

THE war has taught some facts with regard to typhus fever, the principal of which is that it is mainly spread by means of infected lice, and consequently there should be no great difficulty in preventing its dissemination. Cleanliness prevents the spread of typhus, as it is primarily and eminently a disease of dirt. As is well known, typhus fever prevailed extensively in certain of the prison camps of Germany owing to the flagrant and inhuman disregard by the German military authorities of the recognized ethics of civilized warfare. Little or nothing has been heard of these outbreaks from German sources until recently, when German medical papers are beginning to come into allied and neutral countries. In the *Archiv für Schiffs u. Tropen Hygiene* for August, 1918, Drs. Stojan Kirkoviz and Vladimir Alexieff give an account of typhus fever in a war prisoners' camp.

At the end of 1914, and in the beginning of 1915, the authors had the opportunity of studying in one of the camps a simultaneous outbreak of typhus and recurrent fever. There were thirty-three cases of double infection. In eight instances infection must have occurred of both diseases at practically the same time, since the pyrexia due to typhus was grafted immediately, or after a slight interval, upon that caused by the first paroxysm of recurrent fever. In other cases there was an interval of some days before the cessation of the latter and the appearance of symptoms suggestive of the former. It is supposed that these became infected with typhus by contact with other patients during removal to hospital. In all cases the symptoms of recurrent fever preceded those of typhus, and consequently the course of the epidemic was such that while in the beginning there was a predominance of cases of recurrent fever over typhus, the relative proportion at the end was the reverse.

Regarding the fall of blood pressure, which is a distinctive feature of typhus fever, Drs. D. Danielopolu and D. Simici, writing in the *Archives des Maladies du Cœur* for January, 1918, explain the marked fall in blood pressure which occurs in typhus fever by the damage done to the adrenals, with the concomitant results of vasodilatation and diminution of peripheral resistance. In a paper contributed to the same journal for February, 1918, Danielopolu records his conviction that the blood changes occurring in typhus fever follow precise rules, and have an important prognostic value.

Lastly, Drs. B. Moellers and G. Wolff, writing in *Deutsche medizinische Wochenschrift*, June 20, 1918, deal with the possibility of applying to typhus the principles of prophylactic inoculation which hold good for other epidemic diseases. The authors confined themselves to attempts to obtain active immunization by repetition of the method followed by several investigators, that of utilizing as an inoculum the blood of patients actually suffering from typhus fever. The main modification introduced is the employment of 0.2 per cent. formalin as a means of

preserving the infected blood which forms the inoculum. They claim the following results from this treatment: (1) Prophylactic inoculation against typhus fever with formalinized blood is quite as harmless as that against typhoid fever or cholera. (2) Although it offers no absolute protection against all possibility of infection, there would appear to be a diminution of both incidence and mortality among those inoculated, but even so, no relaxation of the campaign against lice, even among the inoculated, is permissible. (3) In certain cases it has been possible to immunize guinea pigs against inoculation with virulent typhus blood by means of preliminary injections of formalinized typhus blood. (4) Of over 650 persons who underwent this prophylactic inoculation, 11 contracted typhus; of these, 6 acquired the disease within 3 months, and 5 between 3 and 8 months from the time of inoculation. Death occurred in one case; the remainder recovered. Besides the 11 mentioned above 4 individuals who had only received two injections instead of three contracted the disease, as well as six others who were inoculated during the incubation period.

OCULAR SENSIBILITY TO PRESSURE AND ITS CHANGES IN TABES DORSALIS.

THE eyeball in the normal state possesses a special sensibility to pressure, made manifest by a deep-seated acute pain, *sui generis*. It can be aptly compared to deep-seated sensibility of various viscera, such as the trachea, mammary gland, ovary, and testicle. Ocular sensibility to pressure is largely due to setting into activity of the sensitive nerve endings in the choroid and its appendages and consequently is entirely within the domain of the fifth cranial pair by the intermediary of the ciliary nerves. Ocular sensibility to pressure will become disturbed in morbid processes involving the structures composing ocular tunics and the intraocular substance, but the study of these disturbances is yet to be undertaken.

Sensibility to pressure on the eyeball may likewise be modified in affections of a more general order and more particularly in locomotor ataxia. In this process the changes are, firstly, an increase which constitutes ocular hyperalgesia to pressure; secondly, a diminution which may very properly be termed ocular hypoalgesia to pressure; and thirdly, an abolition which represents an ocular analgesia to pressure. Under the latter term may be included all the variations in minus of ocular sensibility to pressure.

Ocular hyperalgesia in tabes is very uncommon, analgesia being by far the most frequent, being met with in somewhat over fifty per cent. of tabetics and in all the phases of evolution of locomotor ataxia. This analgesia appears to have little or no direct relation with the intraocular tension, the condition of the retina and optic nerve, and in general with the ordinary ocular manifestations commonly encountered in tabes, and, above all, with the state of corneal sensibility.

The ocular analgesia of locomotor ataxia is easily detected, while its frequency and the characters properly belonging to it make it a symptom which when elicited may well serve in the diagnosis of doubtful cases. The pathological interpretation of tabetic ocular analgesia is still hypothetical, but it is quite logical to look for the cause in a ciliary neuritis which may be included among the peripheral neuritides of locomotor ataxia. Probably also the ciliaryneuritis is of a sympathetic type, similar to the visceral neuritides belonging to this parasyphilitic process. Ocular analgesia does not belong to tabes exclusively, as it is met with in local affections and those of a more general order, such as hysteria, in which case it affects the same characters as in tabes.

LITERARY ACTIVITIES OF COLLEGE FACULTIES.

EVERY medical school, large or small, endowed or not, doubtless cherishes the ideal of an all star faculty, every member of which must have done something to make a name for himself and thereby reflect glory on the schools. When a man receives an appointment to a chair it is intimated to him, vaguely perhaps, that he must make good by writing a book or publishing the results of experiments or advocating some policy of teaching and so on. The metropolitan universities have little trouble in fulfilling these ideals by reason of the great reserve of competent men immediately available who can supplement any weak point in the regular faculty. In an older generation the small provincial school got along by adding to the local men professors from metropolitan schools. The system of consolidation of small schools to form a large one and of absorbing the small school has greatly raised the standard of medical education and one is curious to know whether this integration movement has contributed directly to the ideal of a faculty of men of renown. A preliminary survey rather goes to show that such a result is as yet unattained, and that outside the great metropolitan schools the faculties as heretofore comprise a few stars, while the balance of the teaching body, however competent and well known to their special colleagues, have no extended reputation.

By way of contrast, and also to indicate clearly just what is meant, let us select at random a small European medical school, that of Bordeaux, a city of about 300,000 inhabitants. We select only a few of the faculty, the names perhaps comprising men recently deceased. The incumbent of the medical chair, Pitres, one of the leading authorities on neuroses and a former collaborator with Charcot, is also the author of a two-volume work on hysteria and hypnotism, not to mention other volumes. His colleague, Arnozan, is author of a large monograph on medical hydrology. Villar, one of the incumbents in surgery, has published a work on operative surgery and a monograph on surgery of the pancreas. Lefour is author of a monograph on fibroids and pregnancy, Lagrange of one on tu-

mors of the eye, and Loumeau, the urologist, of a two-volume work on his special field. Denucé, with Nové-Jusseraud, has just published a standard work on orthopedics. Better known, perhaps, than any of the preceding are Pachon of the chair of physiology, whose blood pressure apparatus (oscillometer) is the one in common use in France, and the celebrated electrologist and physicist, Bergonié, who incidentally devised a method of electrical treatment of obesity.

POSTINFLUENZAL IMMUNITY

THIS question is naturally fraught with numerous difficulties, for the natural immunity varies greatly with the particular outbreak and the mild or masked attack which confers acquired immunity may have escaped observation. The incidence of a second outbreak is usually smaller than that of the first, although more deadly, and the escape from a second attack may be due to nonexposure. Pseudogrippe, endemic winter grippe, or winter catarrhal fever confers no immunity but rather increased susceptibility, and who shall decide where true influenza leaves off and endemic grippe begins? It is apparent that acquired immunity can be studied only in the first two or three waves of a pandemic. If such is in evidence, is it complete or does the victim develop a mild type of true influenza? If there is protection, how long may it last? The last query is most difficult to answer, but the claim has been made that the victims of 1890 have shown resistance to the disease of 1918 even if they have suffered repeatedly in the meantime from endemic winter grippe. The subject is best studied in institutions which have been visited by successive waves of the pandemic. Not a few reports from asylums and other institutions have apparently shown the presence of immunity.

Falcioni, in *Il Policlinico* for February 2, takes up the subject in connection with an orphan asylum in Rome which was visited a second time in January of this year. The data, which are not given in detail, appear to show the existence of a double tendency to contract the disease anew and to resist a second attack. During the second outbreak the diffusibility was great and the children were smitten almost simultaneously, yet with the same exposure a certain number did not develop a second attack. To offset this view it may be added that an institutional epidemic is not a fair criterion, for, owing to the communal existence and overcrowding, ordinary winter grippe may exhibit epidemic behavior. The endemic form has not been obliterated by the pandemic, for the New York practitioners regard the grippe cases now among us as largely of the endemic type in everything save prognosis. They fear lung complications and hence prolong the convalescence as much as possible. Institutional epidemics are not necessarily part of the pandemic, for they could readily occur in its absence. To prove them to have a pandemic origin it would be necessary for the region to be actually in the grip of a pandemic wave.

ALLEGED POISONING BY MINUTE DOSES OF RHUS TOXICODENDRON.

DR. DE HAAS of Rotterdam describes in the *Nederlandsch Tijdshrift voor Geneeskunde* for January 25 a case of poisoning attributed to the ingestion of a presumably harmless remedy. The latter is a popular homeopathic preparation and has never so far as known given untoward results. The writer was consulted by a woman who was very anemic and who complained of headache of a frontal localization. Evidently he found nothing serious the matter, as she was free from constitutional symptoms. His diagnosis seems to have been anemic headache. No treatment is mentioned. Several days later he was again summoned. The headache had partly disappeared. He noted that the pupils were dilated, reacting freely to light and accommodation. Vision was found normal. Several days later it became evident that some disorder of the eyes was present. The pupils had become sluggish to light and visual acuity was diminishing. An earnest request was made to call in an ophthalmologist, but this was refused with firmness. Soon afterwards, the woman having complained of abdominal pain, it was found that urinary retention was present. The catheter brought away a liter and a half of normal urine. The ocular disturbance had now become so serious that a specialist was called in who made a diagnosis of probable poisoning, such as might arise from lead or arsenic—the actual diagnosis was toxic retrobulbar neuritis. The examination of the urine was quite negative. The author mentions no treatment for the interval, but merely states that a month later the visual troubles had disappeared. Pressed for more enlightenment, the woman confessed that before she had first summoned the doctor she had been taking a homeopathic remedy obtained from a druggist. This proved to be rhus toxicodendron, five drops of a 1-1000 solution (3x in the homeopathic potency scale) three times daily. Search through the literature reveals nothing akin to this case, only local untoward effects being known. It has been shown that 1/1000 mgm. of toxicodendrol, the active principle, can cause a local skin reaction. It has also been stated, but without details, that this substance is toxic to the dog, although many herbivora seem immune. Search of homeopathic literature reveals no data as to toxicity unless we include subjective phenomena. The mother tincture is made from one part of dried plant and two parts of alcohol, and in one day the patient received only ¾ milligram of this mother tincture. The author leaves the solution of the puzzle to his readers.

WAR ILLEGITIMATES IN FRANCE.

LAUMONIER discusses this subject so far as it concerns France in the *Gazette des hôpitaux* for February 20. The dead of France number 1,500,000 on the battlefield and in the military hospitals alone, while the civilian deaths for the war period, greatly augmented by the grippal pandemic, are sufficient to make the gross depopulation 4,000,000. On the other side of the ledger 1,500,000 inhabitants accrue to France through the recovery of Alsace-Lorraine. The kilometric density of population is now but seventy, far too low in comparison with

Germany. In regard to the rate of natality unfavorable influences comprise the social maladies—tuberculosis, syphilis, and alcoholism. But a singular element has been interjected which, while criminal in origin, makes for the other side of the question. This is the generation of a race of bastards as a result of the systematic violation of French women by German officers, who, having first isolated the men of the conquered communities, wrought their will among the women. The cynical justification was that the superiority of German blood would tell in the long run and that some day these spurious children would be found on the German side in any future dispute, and, like the children of legitimacy of international unions, would favor annexation. In other words, rape becomes German propaganda and germanization of the conquered. The French, to meet this argument, were for interruption of all of these pregnancies. But the author's study of the past has convinced him that these half-breeds tend to take after the mother so long as they are reared in their own country. In Alsace-Lorraine Frenchmen with German names are extremely numerous, showing that the influence of the father has been greatly exaggerated, even in a country which has changed hands several times. Further study shows that, whatever their paternity, children of French mothers reared on French soil remain French.

Influenza Nostras.

It seems strange that the useful adjective "nostras," used in the sense of domestic, has never come into use for the ordinary endemic winter grippe which has prevailed among us annually for about thirty years and certainly in special localities for a much longer period. The term "cholera nostras" used in Europe as a synonym for our "cholera morbus" is a very useful term to distinguish the latter from epidemic or imported or Asiatic cholera. There is no implication in using this adjective that the domestic and imported diseases are identical, but it is very difficult to distinguish between them clinically. In the *Brazil-Medico* for February 8 Dr. Ribiero da Silva contrasts pandemic with domestic influenza (*Grippe pandemica e grippe nostras*). As nothing is said of the antiquity of the domestic form we may perhaps assume that he regards it as perennial. The old malady, the one which we know from long experience, is not the pandemic form, and the thoughtful student must become a pronounced dualist. The parallel between the clinical expression of the two affections need not be carried out, for it is or should be sufficiently known to all medical men. There are certain districts in the interior of Brazil in which grippe appears annually in the early autumn or spring which serves as a type of influenza nostras. It varies much in severity and is apt to kill old people by bronchopneumonia. In these subjects the *Diplococcus capsulatus* is found in the lungs in large numbers. This domestic type is somewhat contagious. In S. João del Rey, a locality visited annually by domestic grippe, a small episode of the latter appeared last September. When in November the pandemic reached this locality the same individuals were promptly attacked, furnishing a fine concrete proof of dualism.

News of the Week.

Influenza in the South Sea Islands.—Influenza is reported to have played havoc in the South Sea Islands, Samoa, Fiji, Tonga, and Tahiti having suffered great loss of life. There were about 8,000 deaths from the disease in German Samoa, two-thirds of these being men. It is said that at one time as many as 80 to 90 per cent. of the population of Sidney were lying ill with the disease. Most of the missionaries and 56 per cent. of the Government officials have died. In New Zealand during a few weeks there were almost 6,000 deaths. A Pneumonia-Influenza Commission appointed to study the epidemic in that country characterizes it as one of the gravest calamities which ever befell the people of the dominion. Fearing that if the influenza gained a foothold in the former Bismarck Archipelago or on the mainland of New Guinea it would decimate or even exterminate the native population, the Australian Military authorities at Raboul took extensive steps to prevent such an occurrence by inoculating between six and seven thousand blacks in Raboul, and arrangements were made for sending a steamship with doctors and vaccine through the many islands near New Guinea.

Association for the Study of Children.—The National Association for the Study and Education of Exceptional Children held its annual meeting at the Hotel McAlpin, New York City, on April 30. Among the speakers were Dr. Maximilian, P. E. Groszmann, founder and leader of the Association; Dr. Frederick J. Farnell, examining psychiatrist of the public schools of Providence; Dr. Arthur D. Jelly, examining psychiatrist of the public schools of Boston; Dr. E. Bosworth McCready, associate editor of the *Journal of Sociological Medicine;* Dr. Julius Levy, Director of the Bureau of Child Hygiene of the Department of Health, Newark, N. J.; Dr. Francis N. Maxfield, psychologist, Department Medical Inspection, Newark, and Dr. Ira S. Wile of New York City.

Red Cross to Teach Home Nursing.—The American Red Cross has rented an apartment in a tenement house at 510 West 26th Street, in which the women of the West Side will be taught elementary hygiene and home nursing. If the experiment is successful similar centers will be established elsewhere in the city. Health Commissioner Royal S. Copeland and Dr. John Lovejoy Elliott are cooperating in the enterprise.

Deaths in the Army.—A report from the Surgeon General's office, issued by the War Department, gives the total number of deaths reported during the war to April 29, 1919, as 111,179. Of these 56,632 or 51 per cent. were from disease, 43 per cent. in battle or from wounds received in battle and from other injuries. Of the deaths from disease about 12,000 have occurred since hostilities ceased.

New Site for Orphan Asylum.—The Hebrew Orphan Asylum of New York City has purchased a site for new buildings consisting of 103 acres on 233rd Street in the Bronx, at a cost of $350,000. Plans are being made for the expenditure of $1,000,000 for new buildings which will probably be on the cottage plan with separate buildings

for the hospital, dispensary, and schools. The institution cares for about 12,000 children.

Dr. Frank P. Norbury of Springfield, Illinois, has returned to his home and resumed private practice after having served since August 1, 1918, as Acting Medical Director of the National Committee for Mental Hygiene in New York. Major Frankwood E. Williams, having received his discharge from the Medical Corps of the Army, has resumed his duties in the office of the National Committee for Mental Hygiene.

Dr. Elbert M. Somers has completed his service with the American Red Cross as hospital superintendent in France and has resumed his practice in Brooklyn.

Dr. C. E. K. Vidal of Great Falls, Mont., has been appointed superintendent of the State Tuberculosis Hospital at Galen.

The American Board of Ophthalmic Examinations will hold its next examinations at the Willis Eye Hospital, Philadelphia, June 6 and 7, 1919. The coming examination will be the fifth to be conducted by the Board, which is composed of members of representatives of the American Ophthalmological Society, the Section on Ophthalmology of the American Medical Association, and the Academy of Ophthalmology and Oto-Laryngology. By arrangement with the American College of Surgeons, the Board has become the Ophthalmic Credentials Committee of the College, and conducts the ophthalmic examination of the ophthalmic candidates for Fellowship in the college. Details with reference to the examination may be had upon request from the Secretary, Dr. William E. Wilder, 122 South Michigan Avenue, Chicago, Ill. The Board is doing a valuable work in trying to raise the standard of ophthalmology in this country.

Hospital Bed as Memorial to Roosevelt.—The American Fund for French Wounded, which is prepared to erect a Memorial Hospital in Rheims, announces that friends and admirers of Theodore Roosevelt have raised a sum to endow a bed in the hospital as a memorial to the former President.

Bequests.—The will of John B. Manning makes the following bequests to New York City Hospitals: St. Vincent's Hospital, $25,000; St. Francis and St. Joseph's Hospitals each $10,000, and Misericordia Hospital, $2,000.

By the will of the late Sarah Lamb of Lockport, N. Y., the sum of $500 is bequeathed to the Woman's Medical College of Pennsylvania.

By the will of the late Moses J. Blitz of Philadelphia the income from an estate of $30,000 is bequeathed to the Jewish Hospital for the maintenance of three beds.

County Society again Remits Dues of Men in Service.—The Comitia Minora of the Medical Society of the County of New York has passed a resolution empowering the Treasurer to remit the dues of members in service who so request. Such requests must be filed at once in order that the books of the society may be brought up to date.

Positions for Physicians in Panama Canal Service.—The United States Civil Service Commission announces an open competitive examination, for men only, on June 18, 1919, to fill vacancies in the Panama Canal service, at salaries of $150 a month with promotions up to $300. Applicants must be unmarried, must have been graduated from a recognized medical school whose graduates are eligible for commission in the United States Army, and must have had at least one year's post-graduate hospital experience. Those desiring to take the examination should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C.

Medical Society Elections.—The SOUTH CAROLINA STATE MEDICAL ASSOCIATION, at its annual meeting, held in Florence, April 15-17, 1919, elected the following officers for the ensuing year: *President*, Lieut.-Col. E. W. Pressley of Greenville; *First Vice-President*, Dr. D. M. Smith of Florence; *Second Vice-President*, Dr. O. C. Shecut of Orangeburg; *Third Vice-President*, Dr. C. A. Mobley of Rock Hill; *Secretary and Treasurer*, Dr. J. P. Taylor of Adams Run; *State Board of Examiners of optometrists and opticians*, Dr. E. M. Whaley of Columbia.

The WOMEN'S MEDICAL SOCIETY OF THE STATE OF NEW YORK, at its thirteenth annual meeting, held at the Hotel Onondaga, Syracuse, May 5, 1919, elected the following officers for the ensuing year: *President*, Dr. Elizabeth B. Thelberg of Poughkeepsie; *First Vice-President*, Dr. Florence I. Staunton of Utica; *Second Vice-President*, Dr. Sarah J. McNutt of New York City; *Third Vice-President*, Dr. Matilda K. Wallin of New York City; *Secretary*, Dr. Ethel D. Brown of New York City; *Treasurer*, Dr. Phoebe M. VanVoast of New York City; *Scientific Program*, Dr. Grace N. Kimball of Poughkeepsie.

The FAIRFIELD COUNTY (CONN.) MEDICAL ASSOCIATION, at its 127th annual meeting, held in Bridgeport, April 8, 1919, elected the following officers for the ensuing year: *President*, Dr. George R. Hertzberg of Stamford; *Vice-President*, Dr. Eli B. Ives of Bridgeport; *Secretary*, Dr. C. W. Gardner of Bridgeport; *Treasurer*, Dr. H. B. Lambert of Bridgeport.

New Dean of the College of Physicians and Surgeons.—Dr. William Darrach, formerly professor of clinical surgery, has been appointed dean of the medical department of Columbia University, to succeed Dr. Samuel W. Lambert, who recently resigned. Dr. Darrach sailed from New York with Base Hospital No. 2, May 14, 1917. After serving in various posts he was made chief consulting surgeon at the Third Army Headquarters. On March 7 last he was promoted to colonel for distinguished service. He received his discharge April 12.

Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases.—A stated meeting of this society will be held at 41 East 123d Street on Tuesday, May 13, at 8.30 P. M. Dr. Sidney A. Twinch will read a paper on "Tuberculin in Tuberculous Joint Diseases," and Dr. Lewis Hart Marks one on "Specific Chemical Therapy."

Sailor Brings Smallpox to New York.—The second mate on the coastwise steamer *Desha*, plying between New York and Mobile, was taken from this vessel on April 22 suffering from smallpox. The woman who conducts the boarding house where he stays when on shore leave is also in the hospital with this disease.

Red Cross Formulates Peace Program.—The American Red Cross announces the passage of a resolution at the Red Cross conference at Cannes, agreeing to formulate and propose to the Red Cross societies of the world an extended program of Red Cross activities in the interests of humanity. The resolution provides for the utilization of a central organization which shall stimulate and coordinate the voluntary efforts of the people of the world through their respective Red Cross societies in the development of sound measures of public health and sanitation, the welfare of children and mothers, the education and training of nurses, the control of tuberculosis, venereal diseases, malaria and other infectious and preventable diseases, and which shall endeavor to spread the light of human science and the warmth of human sympathy to every corner of the world.

Dr. Abraham Jacobi's Eighty-ninth Birthday was celebrated on Tuesday of this week. It is one of the privileges of May time to offer our felicitations to Dr. Jacobi on this day each year, and we look forward with pleasurable anticipation to the celebration, eleven years hence, of his first centennial.

Dinner to Mt. Sinai Unit.—The officers and men of Base Hospital No. 3, the Mount Sinai Unit, which was under the command of Lieut.-Col. Howard Lilienthal, were given a dinner at Sherry's on the evening of May 3 by the trustees of Mt. Sinai Hospital. The headquarters of the unit was at Vauclaire, and during the period of hostilities it cared for 14,500 patients, among whom were 3,500 gassed men. There were 1,700 operations performed by the unit, with a mortality of less than 1 per cent. The medical mortality was about 3 per cent.

Spain Honors Mme. Curie.—King Alfonso has signed a decree awarding the Great Cross of the Civilian Order of Alfonso XIII to Mme. Sklodowska Curie, the distinguished French scientist, chief professor in the faculty of sciences of the University of Paris. Mme. Curie was the discoverer of polonium and codiscoverer with her husband of radium.

Obituary Notes.—Dr. MORTIMER FRANK, a graduate of the University of Illinois Medical Department, in 1901, died from an apoplectic stroke at his home in Chicago, on April 28, aged 45 years.

Dr. ZACHARIAH T. SOWERS, a graduate of George Washington University, Department of Medicine, in 1869, died at his home in Washington, D. C., on April 23, after a long illness, at the age of 73 years. He was a Civil War veteran, a member of the Medical Society of the District of Columbia, of the National Geographical Society, and the Anthropological Society. He was president of the Washington Foundling Hospital, and on the visiting staff of the Garfield and Providence Hospitals.

WILLIAM TYLER SMITH, a graduate of Jefferson Medical College, Philadelphia, in 1883, died at his home in Sheridan, Ore., on April 17.

Dr. FREDERIC A. WILLIAMS of New York City, adviser of the New York State Insurance Fund, died as the result of injuries received in an automobile accident, in Atlantic City, on May 2, aged 49 years. He was formerly on the staff of the Hudson River State Hospital, at Poughkeepsie.

Correspondence.

THE ADMINISTRATION OF ARSPHENAMINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It appears that there is a lamentable want of care on the part of many physicians who administer arsphenamine as to the concentration of the drug used and the time required for administration.

The Hygienic Laboratory receives many complaints in regard to untoward results from the administration of arsphenamine made by various American producers. When careful investigation is made it is almost invariably found that the drug has been used in a solution that is too concentrated, and that it has been administered too rapidly. We have reports of a dose of 0.4 gm. being given in a volume of as little as 25 c.c. and injected within 30 seconds. Such practice is abuse, not use, of a powerful therapeutic agent.

If, in addition to the usual precautions as to the use of perfect ampules and neutralization, physicians would give the drug in concentration of not more than 0.1 gm. to 30 c.c. of fluid and allow a minimum of two minutes for the intravenous injection of each 0.1 gm. of the drug (in 30 c.c. of solution), the number of reactions would be very materially reduced. This would necessitate from 90 c.c. to 180 c.c. of the solution for the doses usually given and would require from six to twelve minutes for the injection.

Any physician who fails to observe these precautions should be considered as directly responsible for serious results that follow the improper use of the drug.

G. W. McCOY,
Director, Hygienic Laboratory,
U. S. Public Health Service.

WASHINGTON, D. C.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, April 9, 1919.

A Health Conference of Insurance Organizations.—It goes without saying that since the National Insurance Act, and to a certain extent since the institution of Old Age Pensions, the position of all the insurance organizations with regard to the practice of medicine has been a very intimate one. It is a little unfortunate that it has not always been quite a friendly one, but the proceedings at a recent Health Conference, held by these organizations and other bodies engaged in social work, were of such a practical nature that we look forward to much valuable cooperative work in the future. The presidential address to the conference, delivered by Mr. P. Rockliff, indicated that every endeavor would be made by the Government in the new Ministry of Health Bill to meet the views of the Friendly Societies. Now it is believed that every endeavor will also be made by the Government to meet the views of the medical profession, while it is the Friendly Societies with whom the medical profession are sometimes upon strained terms. Mr. Rockliff's speech suggested that mutual understanding was

approaching. The Friendly Societies, it will be understood, are those groups of mutual aid members who, by payment to a society, secure for themselves medical assistance and treatment; but as, under the National Insurance Act, such assistance and treatment has to be furnished through the medical profession by a system of panels, the payment of the panel doctors proceeds from these mutual aid groups, *i.e.* it proceeds from the patients, the employers, and the State, indirectly through the Friendly Societies. The Friendly Societies resent the fact that they have, or consider they have, no control over the doctors whom they pay, and from this feeling arises most of the opposition which the medical profession suffers when the improvement of panel conditions is in question. For the doctors, of course, see that they are neither employed by nor paid by the Friendly Societies, but their employment arises as officers of the National Insurance Act. It is, therefore, significant that at the National Health Conference of Insurance Organizations of Social Workers no criticism was made by the president of existing panel methods. If the parties to the misunderstanding between the panels and the Friendly Societies will be silent peace will come sooner.

The next speaker at the conference was Sir Laming Worthington Evans, the Minister of Pensions, who said that arrangements were being made by the Ministry of Pensions to take over orthopedic hospitals from the Army and to establish out-patient clinics in surrounding towns and districts under the direction of the surgeons attached to the orthopedic hospitals. How much work lies before the Ministry of Pensions can to some extent be realized by the figures which he gave. With regard to training, he estimated that the classes falling within the terms of the Pensions Warrant numbered about 350,000 men. He did not mean that the whole of these 350,000 men desired to receive, or were even qualified to receive, training, but from among these we should expect to find a large number for whom training ought to be provided. "For example," he said, "there were 24,000 men who had lost a limb by amputation; there were 36,000 men who had suffered from neurasthenia; many of these would require outdoor employment; there had been 60,000 suffering from chest complaints, including tuberculosis, and there had been 54,000 men suffering from heart trouble who might have to change their occupation if it previously called for heavy physical strain."

Sir Kingsley Wood then introduced the subject of the relation which medical research should bear to the State, and said that the House of Commons had unanimously supported the establishment under the new Health Bill of a great Research Department. Sir Walter Fletcher, the secretary of the Medical Research Bureau, followed, and no doubt many members of the public thought that it was his bureau to which allusion was being made. This, however, is not the case. Sir Walter Fletcher's bureau, the Medical Research Bureau, which came into being in connection with the National Insurance Act, is now to be transferred to the ægis of the Privy Council and, instead of working in the interests only of those benefited by the National Insurance Act, it will now take on international activities. Under the new Health Bill a *new* Research Department will be founded, and its necessity is well indicated by the fact that the cost to the State of the recent epidemics of influenza is said to have been £120,000,000, while during the year the State contributed £65,000 to the existing Medical Research Bureau. Sir Walter Fletcher's address was an excellent exposition of his text that, "If the war had taught us nothing else, it had taught us the dependence of the State for its existence on scientific work." He ran rapidly through the benefits that had occurred to the human race through the work of medical research, which he said was none the less done by a small army of unseen, little-known workers, and practically the whole of the work was unpaid. In connection with this fact he said that while in England a man would receive £100 to solve an important scientific problem and spend £90 on the actual materials required for research, in the United States the endowment for research was measured by millions. Sir Walter Fletcher was followed by General Sir William Leishman, who spoke of the part that had been played by hygiene in keeping our armies in a fit condition in the field and in warding off epidemics which in the past had so often brought fighting to a standstill. He enumerated directions in which medical research had been especially valuable in times of war, while he indicated in the times of peace the medical department of the army would be the best body available for carrying on works of research. The officers of that department, as he pointed out, had the advantage of being able to observe for long periods bodies of men under varying conditions of climate and in an environment that does not obtain in civil life, but which is particularly suitable for research.

The conference was held at the Central Hall, Westminster, under the auspices of the Faculty of Insurance, and may be said to have been promoted by persons who, through their organizations and group movements, can command a great deal of money and can influence a great many votes. The approval with which speakers were listened to, whose one common plea was that money should be poured out in behalf of medical research, should be of good omen for the medical profession.

Vacancies in the Council of the Royal College of Surgeons of England.—The affairs of the wealthiest medical corporation in England, the Royal College of Surgeons, are managed by a council of twenty, two vice-presidents and a president. Two vacancies are occurring by seniority, but Sir Berkeley Moynihan is offering himself for re-election and is sure to succeed. There are five candidates for the second vacancy, of whom Colonel Cuthbert Wallace and Colonel A. H. Tubby have the best chances.

The Dogs' Protection Bill.—A bill for the Protection of Dogs has passed the committee stage, and will now be reported in amended form in the House of Lords. The bill, if it becomes a law in the shape in which it is now amended—in spite, it may be added, of the efforts of the Government—

will prohibit any experiments on dogs, whether conducted with or without anesthetics, having for their object medical research. There has always been acute dislike on the part of the public to the idea that the dog should be used for research or experimentation purposes, and the feeling is so natural that it did not really require the exploiting which it has received at the hands of very many sentimental and some mendacious persons. There is, of course, no rational basis for suggesting that the dog should be exempt from medical experiment any more than another animal except sentiment. If there is anything immoral in the act toward the dog, it is equally immoral toward the horse and the monkey, but the intimate association of the dog with man has prevented reasonable argument in regard to the matter. Physiologists, far from being cruel people, have not the slightest desire to experiment on the dog rather than on any other animal, if only because they are perfectly aware that physiological research, with the dog as a subject, causes enormous pain to the public, even though in the great majority of cases it causes none to the dog. For which reason the important question at issue is: How far is the use of the dog essential to physiological experiment? The leaders of physiological research, if this question were put to them, would unanimously point out that some of the most valuable work which has ever been performed in practical physiology was associated with experiment on the dog. This, of course, is certainly true, and at the present moment there are in England researches being conducted through the medium of experiments on dogs which may have a vastly beneficial effect upon child life, but, of course, until experiments with similar objects have been carried out on other animals than dogs, no one can dogmatically assert that the dog was essential to the experiment. To the medical profession the institution of an act exempting the dog from physiological experiment would be a perfectly welcome proceeding if it were not for two things. The first is the underlying assumption that the physiologist is a cruel person, and the second thing is the fear of dictation from lay authorities upon purely medical points.

The second of the objections to the Protection of Dogs' Bill should today be disregarded. The sooner the medical profession learns to trust the public, for whom, but also through whom, they exist, the better for all. The first objection has its origin also, to some extent, in the medical attitude. Why are not the reasons for the employment of dogs in certain physiological experiments clearly stated? The public talks as if the dog might be spared by using the rabbit, which is herbivorous; the rat, which is too small; the pig, which is unnecessarily large, and the monkey, which is too expensive. Those who desire to stop all physiological experiment again exploit the natural and honorable position of the dog as the friend of man," as a reason for removing the dog from the laboratory, but they forget that this long association with man is actually a quality recommending the dog for certain experiments. What other animal sleeps at home, walks abroad, eats omnivorously, and shares the delights and restrictions of civilization? None. If the experiment turns on a condition of civilized life, the dog is obviously the best medium through which to acquire knowledge.

The Clinical Meeting of the British Medical Association.—This meeting is proceeding successfully. A fairly representative crowd of doctors, military and civil, home and Colonial, are present and some of the proceedings have already been very interesting. A paper by Colonel G. E. Gask on the biology of wounds, another by Colonel T. R. Elliott on gunshot wounds of the chest, another by Colonel F. W. Mott, on war neuroses, and another by Colonel L. S. Dudgeon on bacillary dysentery are among the most important communications yet read, and sufficiently indicate the range of the congress's activity.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, March 27, 1919.

Work of the Pittsburgh Field Ambulance.—Much has been written and said about the great national organizations auxiliary to the army. There are many smaller and individual organizations that have done noble work and among them is the Pittsburgh Field Ambulance, the central committee of which has, from the beginning, found collaborators, inspired with a true spirit of fraternity, who have always worked without compensation. The Pittsburgh Field Ambulance General-director in Paris, Dr. de Gerin, has devoted himself entirely to his task. Wounded and having lost the use of one arm through blood poisoning he has given all his time and strength to aid the sick and wounded poilu.

Since it began its work the Pittsburgh Field Ambulance has presented more than 346,000 gifts to over 700 ambulances, without counting some 13,000,000 sheets of writing paper and envelopes given to enable the men to write to their families. The value of these gifts amounts to nearly 3,000,000 francs. The most interesting of its work is perhaps that which was done in the invaded regions of the Vosges, where more than sixty villages were occupied for four years by the Germans, who robbed the population of everything and carried off the inhabitants to Belgium and Germany.

These "évacués" have been returning gradually since November 11, and find nothing but heaps of stones where their houses formerly stood. The organized devastation by the enemy was so thorough that the inhabitants are in great need of help.

Thanks to the good will of the Service de Santé and the constant facilities it has placed at the disposal of the General Director of the Pittsburgh Field Ambulance, Dr. de Gerin has been able since August last to travel in the region of the Vosges over roads at one time constantly bombarded and to organize the supply of food and clothing in the whole country between Saint-Die and Raon-l'Etape. By his wise forethought supplies were forwarded before the armistice and the numerous gifts were all the more appreciated, since they arrived when most needed.

During the day which immediately followed the signing of the armistice prisoners from the camp at Schirmeck continued to arrive at Raon-l'Etape. They were scarcely covered with a paper shirt and often had only slippers as footgear without socks, and walked forty kilometers in the mountain snow, having received no food on leaving. They were received by the Regional Director, Mr. Bastien, who untiringly distributed food and clothing to these unfortunate men. These released prisoners were mainly soldiers of the Allied forces: Englishmen, Scots, Irishmen, etc.

Dr. de Gerin has visited and conveyed help to more than sixty villages. The destruction everywhere was terrible, and seven villages even to-day are without a living soul. In many other places the evacuated populations are returning, with nothing more than they have on their backs, to find their homes utterly destroyed.

The Pittsburgh Field Ambulance considers that the transition period between the state of war and the economic reorganization will be a most trying one; it has therefore adopted this invaded region and has decided to continue for many months its help to those of the population who have been stripped of everything. They number nearly 50,000 persons. Certain other societies have sent some help. Among them is the Canadian Red Cross, which has responded favorably to Dr. de Gerin's request for the donation of a fine large wooden house, worth about 40,000 francs. This is to be given to the village of Vexincourt and will be used to house the mothers and children while their homes are being rebuilt. The house will afterwards be used as a recreation hall for the young people of the village. The best reward for the constant work done by the Pittsburgh Field Ambulance is contained in the words of many of the mayors of the villages of the region: "Our people feel that they have not been abandoned."

The Crusaders.—When the detailed history of the war can be written, one of the most stirring chapters will deal with the initiative, courage and self-sacrificing spirit shown in countless instances by "Young America." The spirit of these youths was: "Do or Die"; usually they did, often they died. Little by little particulars of individual deeds of daring and abnegation and devotion to duty are coming to hand; and they cause a thrill of national pride in all Americans. The following relates an incident truly typical of this fine spirit: "On November 14, two of us left Venice for Trieste to distribute underclothing and boots to Italian prisoners who were pouring in from the neighboring concentration camps, the conditions at which were appalling beyond belief. The number of ex-prisoners varied from day to day. One day when we were there 105,000 arrived. We fed 30,000 per diem, and the English Red Cross about the same number. We gave clothing and, in many cases clothing and boots, to 30,000 men. Three young American Red Cross workers, Messrs. Rodgers, McConnell, and Dalzell, had in mid-August started from Venice with a motor-kitchen to feed the Italian troops in the trenches. When the Italian offensive began, they managed to secure a camion, provisioned it, and taking it in tow, made their way across the Piave and trundled into Trieste (flying a white flag between Old Glory and the Italian one) before the Austrians had evacuated the city, and were feeding the starving prisoners in less than an hour after arrival. It is to be hoped that great credit will be given in recognition of the "sand" shown by these gallant boys from New York and Boston, for their prowess in practical philanthropy."

The Scottish Women's Hospital at Royaumont, which was started on November 30, 1914, closed its doors this week. During the four years 8,752 French and Allied soldiers and 572 civilians have been cared for by its personnel, and 7,204 operations have been performed. The hospital material, including three *x*-ray installations and the outfits of three operating theaters, has been despatched to the Hôpital Saint-Sauveur, Lille, to replace equipment removed by the enemy.

The death rate in Paris during the past week was below the normal. There were 998 deaths, as against 1,133 in the previous week. The average for the season is 1,071. Grip was responsible for 100 deaths, and 161 were credited to diseases of the respiratory organs.

The American public health experts who are in Paris on their way to Cannes to attend the conference of the Committee of Red Cross Societies, beginning on April 1, were guests at a dinner given on Tuesday evening by Henry P. Davison, chairman of the committee. In thanking his compatriots for coming across the seas to devote themselves to this new international movement in the interest of humanity, Mr. Davison paid tribute to the enthusiasm with which the leading French specialists have joined in the movement, together with the foremost experts of Great Britain, Italy, and Japan.

7. Prevention and Treatment of Seasickness.—Nathan Rosewater suggests the following method of preventing seasickness, which he has employed in a number of cases with perfect success. He points out that to prevent seasickness or carsickness treatment should be begun preferably one or two days, or at least a few hours, before sailing or traveling, and should be continued during the trip so that nausea, dizziness, and vomiting may be prevented. To this end, the patient should be treated for fully one or two days before sailing by emptying the bowels and maintaining a constant preponderance of peristalsis to prevent the overbalancing of the peristaltic forces by those of antiperistalsis, and that preponderance should be kept up during the trip. Since the greatest tendency to antiperistalsis would be after the stomach was full, a tablet of one-sixtieth grain of strychnine sulphate and one of one two-hundredth grain of atropine sulphate should be given one hour before

meals three times a day, and a tablet of aloin, belladonna, and strychnine each night for two nights before going aboard. In this way the normal, but often insufficient, peristaltic force of stomach and bowels is increased and the antiperistaltic forces are prevented from overpowering the normal peristalsis. The author's experience has led him to conclude that the prevention and cure of seasickness by obtunding drugs is neither practical nor advisable. He remarks that no time like the present may ever again be offered to try this method on a large scale, under army discipline and medical supervision.

5. Tonsillectomy in Myositis and Arthritis.—H. I. Lillie and H. R. Lyons discuss the results of tonsillectomy, as reported in November, 1918, in two hundred consecutive cases which were operated on between July 1 and December 31, 1917. Of these patients, 87 were 30 years of age or less, and 113 were over 30, the average age being 30 years. Of those not over 30, 81.6 per cent. were better after tonsillectomy; and of the second group, who were over 30, 77.7 per cent. showed improvement. Improvement was also reported in four out of ten cases of chronic disease, the patients being invalids at the time of operation. In the entire series only 57.7 per cent. of the patients gave a history of tonsillitis. The authors summarize the results of their observations and the reports of the patients' condition as follows: (1) It is justifiable to advise a tonsillectomy in every frank case of myositis or arthritis. (2) A marked improvement may be assured from tonsillectomy alone in 79 per cent. of all cases. (3) It is necessary to remove all possibility of dental sepsis; by so doing a larger percentage of patients will be improved. (4) The duration of the myositis or arthritis is a factor in the ultimate results, although benefit and even complete cure is obtained in some long standing, chronic cases. (5) Forty per cent. of the patients with chronic myositis or arthritis who are invalids will respond favorably to tonsillectomy. (6) The size of a tonsil has no bearing on its possibility as a focus of infection. A careful expression of the tonsillar crypts and a history of throat trouble associated or not associated with the myositis or arthritis is essential in the diagnosis. (7) An absence of a history of diseased tonsil in no way eliminates the organ as a focus of infection. (8) A clean tonsillectomy, with the removal of the plica tonsillaris, is necessary in every case.

5. Some Points in the Treatment of Complicated Influenza. Captains A. J. Eagleton and H. H. Butcher.

3. Left Scapular Pain and Tenderness in Heart Disease and Distress.—John Parkinson submits the results of observations made on fifty cases in which soldiers complained of pain below the left breast which went through to the back or under the left shoulder blade. The scapular pain did not seem to occur in the absence of submammary pain. In character it was sharp and stabbing, or dull and aching, and of gradual onset. In a few cases, this scapular pain began at the same time as the submammary, but in most cases it had been gradually superadded after the lapse of some months or years. As a rule, exertion was found to be the exciting cause. The most constant accompanying feature was shortness of breath; there were also frequently palpitation, dizziness, and general weakness. The author draws attention to the fact that the pain of heart affections may be accompanied by hyperalgesic areas on the posterior as well as on the anterior surface of the chest. In the present series 28 out of 100 consecutive cases complained of pain on the left side of the chest in front and in the left scapular region, and of these 10 showed hyperalgesia on the posterior surface of the chest, involving in every case the lower part of the scapula, though sometimes extending far beyond it. Parkinson remarks that the pain and hyperalgesia described arise from the heart and that in the absence of physical signs of heart disease, the rheumatic history (20 out of 50 cases gave a history of rheumatic fever), the relation to exertion, and the accompanying shortness of breath, indicate at least some physical impairment or functional disorder of the heart, cases showing an extension down the left arm providing additional evidence. The localization of pain and hyperalgesia can only be interpreted on the basis of referred pain in visceral disease. It may be that our ideas upon this subject have been influenced too much by the study of angina pectoris, where the hyperalgesia is often evanescent and the segments involved are the lower cervical and upper two or three thoracic. In chronic heart disease, on the other hand, the hyperalgesia may be present week after week and the segments involved are at a lower level of the spinal cord. From these observations the author concludes that: (1) Pain at the lower angle of the left scapula often supervenes in the course of chronic pain below the left breast, especially when this is severe and long standing. (2) The causes of left submamary, as also of left scapular pain, include valvular and myocardial disease, arterial and renal disease, especially with high blood pressure, functional heart disorders with or without nervous symptoms, and general ill-health where the symptoms suggest cardiac distress. It is therefore present in many cases of "soldier's heart." (3) The sixth thoracic spinal segment, alone or in combination with the fifth, supplies the submammary and infrascapular regions where pain is commonly felt in these heart affections. The accompanying hyperalgesia may be limited to the distribution of the sixth, or fifth and sixth segments, but it often extends to a larger area and occasionally even to that representing most of the segments of the thoracic cord. (4) This submammary pain and hyperalgesia of chronic heart affections with extension to the left scapula forms a contrast in many respects with the sternal and supramammary paroxysmal pain of angina pectoris with extension to the left arm. (5) If hyperalgesia persists or recurs frequently in the course of chronic heart disease or disorder, it indicates a new and troublesome phase. Hypersensitive tissues are not merely concomitant, they induce and supplement pain. It is now provoked even by slight pressure or tension, such as by lying on the left side or turning over in bed or by taking a deep breath, which otherwise would not produce characteristic cardiac pain.

3. Resuscitation Work in a Casualty Clearing Station.—Major Richard Charles and Captain Arthur F. Sladden report the results of resuscitation work in a tented casualty clearing station on the Western front during the three weeks from September 27 to October 15, 1918. During this period 2,823 wounded were admitted and 903 operations were performed. The authors first draw attention to the value of gas and oxygen anesthesia, given by means of a Boyle's apparatus; this was found to be of great assistance in badly shocked cases and in severe gas infections. In order to avoid the onset of gas gangrene, everything was done to effect quick resuscitation. The lines of treatment followed were those usually employed: warmth applied by hot air, from a paraffin stove, ventilating over the patient into his blankets, and from hot water bottles, was the most important element. Water, sweetened lemonade, and other mild drinks were given to quench thirst, but in many cases of shock and abdominal wounds in which vomiting was persistent, it was necessary to prevent excess of drinking. Morphine, heroin, and camphor were all administered when desirable; so far as possible, however, morphine was not given in larger doses than ¼ grain once in twelve hours. Intravenous injections were largely used in the worst cases. Gum infusion was given unless there was obvious bleeding not controllable by mechanical means, when it was thought better to avoid methods which increased the blood pressure; and in urgent cases blood transfusion was preferred. Operation was done as soon as possible. As a general rule, blood transfusion was reserved for the postoperative stage when all bleeding points had been secured. The authors state that although this work was done under conditions of stress and the treatment was controlled by simple clinical methods of observation only, they do not think a discussion of results is thereby invalidated and they conclude that: (1) Resuscitation methods such as have been developed during the war are of the utmost value in war surgery and will be equally applicable in the every-day surgery of accidental injuries and in obstetric work. (2) Gum infusion is an advance on the infusion of normal saline, and may enable a patient who has not lost blood excessively to be operated upon successfully. It is not evident that the benefit due to gum can extend over more than a few hours. (3) Where hemorrhage is severe, blood transfusion is the only reliable treatment, and should be given without delay. In such cases it is much superior to gum. In blood transfusion no important difference was found between whole blood and citrated blood. (4) Previous to transfusion a blood-grouping test ought to be done in every case. If possible, the donor should be of the same group as the recipient; failing that, recourse must be had to a Group IV donor. (5) The authors wish to emphasize the need for observing the strictest surgical aseptic technique toward donor and recipient. The donor must be free from known general infections, such as syphilis or malaria, in so far as can be ascertained by inquiry.

6. Preliminary Note on the Response of Calcium Shown in Maniacal States.—Captain T. C. Graves has made some observations on the effect of calcium in persons suffering from various degrees of excitement, and for this purpose he chose the lactate as the most suitable salt. He found that the action of the drug became evident during the twenty-four hours following its exhibition. The acute mental symptoms were alleviated without the production of the stupor so commonly observed after "sedative" drugs, and the circulatory response was equally interesting. Instead of the rapid, at times almost uncountable, pulse with its flaccid artery and low variable systolic pressure, the pulse became slower, the artery normally constricted, and the pulse wave stronger, indicative of an improved action of the ventricular myocardium. The action of the drug was equally satisfactory in the distressing restlessness and excitement of agitated melancholia and confusional states as with the simple mania, and cases in which influenza had been assigned as the principal cause reacted well and are making good progress toward recovery. In other cases, in which recovery can hardly be expected on account of the duration of the mental disorder, the acute symptoms have been ameliorated. Captain Graves has given 10 grains of the drug three times a day with food until a response has been obtained, when the dose has been reduced to 5 grains. In one case of agitated melancholia, in addition to the doses by day, one or two doses were given at night. In one case of mania with diarrhea, not only was the restlessness and excitement allayed, but the number of stools passed fell from six to one. No untoward effects have been observed and the author remarks that with the small doses employed these can hardly be expected if careful observations on the pulse are made.

4. Causes and Consequences of Disturbances of Respiratory Rate and Rhythm.—J. C. Meakins first says a few words concerning the normal regulation of respiration and after the review of the regulation of breathing mentions some of the more important variations which occur. These variations may be of depth, or of rate, or a combination of these. 1. Normal rate with greatly increased depth, as in severe diabetic acidosis. 2. Diminished rate with little change in depth, as in morphine poisoning. 3. Increased rate and increased depth, as in severe muscular exertion. 4. Increased rate and diminished depth, as in gas poisoning and pneumonia. 5. Periodicity of rhythm or Cheyne-Stokes breathing. The following are one or two of the more important changes: 1. The respiration of diabetic acidosis is well known to all of you. The deep stertoric breathing gives abundant evidence of increased total ventilation. During the early stages of the acidosis the formation of ammonia and eliminative power of the kidneys keep the H-ion concentration in gross equilibrium. When, however, these fail and the H-ions increase, the respiratory center is stimulated and showers impulses to the subcenter to increase the pulmonary ventilation. The points of the Hering-Brener reflex widen; each respiration becomes deeper in the vain attempt to eliminate enough CO_2 to return the H-ion concentration to normal. Meakins wishes to emphasize the character of the breathing of true acidosis, the enormous depths of the individual respirations. 2. The action of morphia upon the respiratory center is to depress it or to make it less sensitive to the action of CO_2. The alveolar CO_2 and the CO_2 content of the blood are raised. This causes an increase in the CO_2 capacity or "alkaline reserve" of the blood, due apparently to the passage of alkali from the tissues into the blood. 3. In severe muscular exertion there is an increased production of CO_2 and lactic acid. This quickly increases the H-ion concentration of the blood, and there is an immediate response of the respiratory center to reduce this by increased elimination of CO_2. This elimination is first accomplished by the widening of the points of the Hering-Brener reflex, or in other words, an increase in the volume of the individual respirations. Eventually this will be supplemented by increase of the rate. 4. It is with the type in which the respirations are rapid and shallow that Meakins deals particularly. The main problem of Professor Haldane, Captain Priestley and himself was to investigate the respiratory disturbances following pulmonary irritant gas poisoning. While it is now generally admitted that in acute gas poisoning the chief danger to life arises from impaired oxygen supply to the tissues, there are several points which require to be elucidated. In the first place, it became more and more evident that the symptoms in the gas poisoning cases were similar to

a group of symptoms occurring also in the cases classified for military purposes as "irritable heart" or "disordered action of the heart" and diagnosed under various headings in civilian practice. In the second place, it was found that though the symptoms on exertion were ameliorated during the breathing of oxygen, they were not removed, and that certain very marked objective symptoms persisted, even when oxygen was breathed. Of these symptoms the most striking was excessive frequency, combined with abnormal shallowness of breathing. In a normal individual the breathing becomes deeper, as well as more frequent, on exertion; and usually the increased ventilation of the lungs is attained by increasing the depth, rather than the frequency, or breathing. In the patients, on the other hand, the increased ventilation was attained mainly by increased frequency, so on ordinary exertion, such as walking, the breathing went up to sixty or seventy a minute, whereas in a normal individual there is usually very little increase in frequency, but a very large increase in depth. The shallow breathing seemed to be in some way connected with the signs already referred to, of distinct anorexia, particularly o.. exertion. The next step was, therefore, to endeavor to discover the connection. For this purpose the investigators devised an apparatus for artificially limiting the depth of breathing in a normal subject. With it they were not only able to regulate the depth of breathing without interfering with the rate, but they could obtain a graphic record of the actual volume and rate of the respiration. By means of their apparatus they could completely reproduce the classical rhythm of Cheyne-Stokes breathing and there could be no doubt that in some way it was due to anorexia. The chief interest in the matter, then, lies in the consequences or the deleterious effects of rapid shallow breathing, which if persisted in beyond a certain degree produces an increasing anorexia, which in turn accentuates the rapidity of the respiration. In this manner a vicious circle is established which will evidently produce a condition incompatible with life. Although this condition has been chiefly investigated in relation to patients recovering from irritant gas poisoning, other striking and important examples may be cited. Perhaps one of the most urgent is pneumonia. As yet the therapeutic value of CO_2 in certain respiratory diseases has not been extensively investigated. The theoretical indications are that it has a definite field which has been very little worked. The use of oxygen has passed through many phases of enthusiasm and condemnation. But, like any other method of treatment, it has to be used with intelligence and with a realization of what oxygen can and cannot do. The usual method of spraying the atmosphere near the patient with a stream of oxygen is absolutely useless and is money thrown away. If oxygen is to be used with best effects, it must be early in the stage of blue cyanosis and in a proper manner. By enriching the oxygen in the inspired air by four or five liters a minute the maximum effect of oxygen will be obtained. This oxygen, however, must be intimately mixed with the inspired air by means of a proper mask. Furthermore, the oxygen must be given continuously. A very satisfactory means of administering oxygen in this way has been devised by Haldane for use in the treatment of acute gas poisoning. This has been so modified that it can be carried in the stretcher and oxygen used as long as is necessary. Meakins points out that in venesection we have therapeutic measure little, if any, secondary in importance to oxygen in these conditions. When cyanosis is well developed and the pulse begins to fail, it is almost certain evidence that the right heart is overburdened and that the venous pressure is too high. If this be not relieved by bleeding, shock and collapse of the cardiovascular system soon will follow with all the attending phenomena of concentration of the blood, progressive diminution in the CO_2 capacity, or alkali reserve of the blood, or to deeper effects of which CO_2 is an index. In order to relieve this condition of impending cardiac and vasomotor failure, venesection is of prime importance.

8. So-called Trench Mouth and Other Manifestations of Vincent's Disease as a Spreading Infection in Canada.—G. F. Laughlen, W. P. Warner and H. A. Holmes point out that during the past two years a number of articles have appeared in British and American medical journals bearing on Vincent's disease of the gums, which in the majority of cases is primary to Vincent's disease elsewhere, and seems to have attracted but little attention prior to 1917. Since then the so-called "trench mouth" among the overseas troops has been identified as Vincent's disease, and many statistics are now available. Statistics, however, seem to be largely wanting in the United States and Canada, and Greeley, *American Journal of the Medical Sciences*, May, 1918, says that he knows of no statistics to show the frequency of Vincent's disease in the United States. The authors state that as a result of investigation during the recent months they have been able to ascertain that Vincent's disease is of more frequent occurrence than is generally suspected. They have found that the disease is prevalent among the civilian population and among soldiers who have not served overseas, although many cases recur in returned soldiers who have suffered from so-called trench mouth overseas. Others develop for the first time after their return to Canada in men who have not suffered from affection of the mouth or throat overseas. Several of their cases showed the lesions about the teeth and tonsils and ulcerative areas tending to spread backward from the molar teeth. The involvement of the tongue is of special interest, as it is very rare. They have records of a case which was admitted to the Toronto General Hospital on January 3, 1914, suffering from an ulcerated condition of the mouth. The ulcers involved tonsils, gum margins, cheeks and right side of the tongue, where it lay up against the last molar tooth. In their experience the diagnosis of Vincent's disease from smears is comparatively easy. They have made smears from the throats of individuals who did not show any lesion and from sloughs which so frequently occur following tonsilectomy. Although spirochetæ and bacilli were present in a few of these smears, the microscopic picture could not well be confused with that given in Vincent's disease. The organisms common to this disease, namely, *Bacillus fusiformis* and *Spirocheta macrodenis*, lose the stain in Gram's method. They have found Gram's stain unsuitable for the demonstration of the spirochete, unless special care was taken in counterstaining. A diagnosis of Vincent's disease cannot be made from cultures alone. Smears were made from swabs sent to them for the culture of diphtheria bacillus and fusiform bacilli, and spirochetæ were found. McKinstry, *Practitioner*, July-December, 1917, states that the disease does not appear to be highly infectious. That the disease occurs in epidemics there can be no doubt. A number of cases came under the notice of the authors, who had been receiving the treatment for syphilis in the form of diarsenol intravenously without any improvement in a concurrent Vincent's disease of the mouth. They desire to emphasize that a correct understanding of the nature of the disease is the all-important factor in the treatment. If the case is mistaken for syphilis, the treatment is usually insufficient to effect a cure. A positive Wassermann test, though it bears a relationship to Vincent's disease, is often present. The authors deplore the fact that literature on the subject is lacking in the United States and Canada. Their investigations have led them to believe that Vincent's disease of the gums is more common and more often undiagnosed than Vincent's angina and that this is by far the most common site of the primary lesions. Vincent's disease seems to be on the increase and affects the health of soldiers as well as the civilian population. As it is a curable and communicable disease, it is of the highest importance that it should be recognized in all its manifestations.

Berliner klinische Wochenschrift.

February 24, 1919.

Alimental Anemia in Nurslings and Early Childhood.—K. Blühdorn refers to the well-known researches of Bunge and attempts to show that the development of alimental anemia presupposes a constitutional anomaly. Insufficiency of a provision of congenital iron plays an important part. Besides this, the writer invokes the nefarious influence of a limited and abusive use of milk (elimination of alkali). Other various factors of infectious or toxic nature may readily favor an exhaus-

tion of the hematopoietic organs, thus having an unfavorable influence on disease. There are some very common hybrid forms both to the alimental anemia and that due to a toxi-infectious factor. From the viewpoint of treatment, the amount of milk consumed should be watched and a mixed diet, rich in salt, is to be ordered, while toxi-infectious influences are to be guarded against.

The Treatment of Influenzal Pneumonia.—H. Kohn raises his voice against the conclusions of a paper published by von Frey, which advises discarding a cardiotonic treatment and adopting a vasotonic one. The writer always combines digitalis with opiates and also quinine given hypodermically.

Clinical Considerations on Myopia.—H. Beckers reviews the various theories relating to myopia. He believes that this affection is in fact a mild dioptric astigmatism (not a corneal one), and if this state of affairs is not recognized in time and if a proper cylindrical lens does not neutralize the vision, prolonged accommodation finally ends in myopic astigmatism. Correcting glasses, on the contrary, prevent the development of myopia, the writer claims.

Münchener medizinische Wochenschrift.

February 21, 1919.

The Treatment of Inflammations with Protein Bodies, and Inhibition.—E. Starkenstein develops to an extreme degree the modern notion of the nonspecific treatments with sera, various albumins and even colloidal preparations and the most varied chemical products. He says that the idea of a particular specific action of each and every medicament should be discarded, in order to study the total action exercised on the organism, likewise the reactions which take place in all the tissues, and, lastly, the manifestation of the changes taking place in the general state at the *locus* of the pathogenic agent. From this general viewpoint the writer studies the influence of numerous products on conjunctival edema following irritation produced by essence of mustard. An inhibitory action on inflammation was thus made evident for methylene blue, fuchsin, eosin, colloidal silver, and subcutaneous injections of milk. Yet more. A physiological solution of sea-salt, likewise distilled water, possessed a similar action (the weakest action belonged to an isotonic salt solution, the action being reinforced by + + hyper or hypotonic solutions). The fundamental action of this antiphlogistic action was found to be due to a decrease of the vascular permeability. This fact is proved by the delay in the appearance of coloring substances in the anterior chamber of the eye of rabbits, when the animal is under the action of the drug. Inversely, the urinary elimination of the coloring substances (for example, fluorescein) is hastened by this vasotonic action on the vessels. Certain toxic actions—strychnine, for example—are functionally decreased by a preliminary injection of milk, calcium chloride, or atophan. This is also due to the general vascular impermeability as well as the early renal elimination. The action on poisoning by the phenols is quite the same.

Deutsche medizinische Wochenschrift.

February 20, 1919.

A New Radiological Procedure for Abdominal Diagnosis.—A. Schmidt backs up the results obtained by Goetze, by gas insufflation of the peritoneum in order to facilitate radio diagnosis. He maintains that the procedure is inoffensive and may be of the greatest utility. Hepatic and gall-bladder affections are those which give the most satisfactory results. Enlarged spleens show up extremely well. The outline of the stomach, brought out by insufflation of the organ, has permitted the writer to make an early diagnosis of carcinoma of the lesser curve in several instances, later on confirmed by operation. The writer offers several drawings made from the most characteristic radiographs taken by him. He likewise studies the field of usefulness of this procedure and states that insufflation of the peritoneal cavity can be combined with the introduction of a laparoscopic tube, thus allowing direct inspection of the viscera which can be compared with the radiological picture of their contours.

Radiological Diagnosis by Means of Pneumoperitoneum.—E. Rautenberg offers a paper on the above subject and puts forward the question of priority. Cases of considerable diagnostic difficulty which have been settled by this procedure are particularly diseases of the liver. The writer also reports some instances of splenic and renal morbid processes which were diagnosticated by this method.

A Familial Affection Resembling Acromegalia, Involving the Skeleton More Particularly.—C. Oehme has had under observation four sisters who presented certain symptoms appearing at puberty, consisting of a diminished development of the secondary sexual characters, an excessive growth in width of the bones of the limbs, particularly of the forearm and legs, with a moderate hypertrophy of the soft structures of the limbs as well. There were no facial changes nor radiographic evidence of morbid change of the sella turcica. The writer completes his paper by a general discussion on the possible part played by the hypophysis in the production of this morbid condition.

La Presse Médicale.

March 6, 1919.

Bacteriological Diagnosis of Diphtheria.—According to Costa, Troisier and Dauvergne, the diagnosis of diphtheria is very simple—too simple in fact. A smear of tonsillar mucus is placed on the surface of a tube of coagulated serum. In twenty-four to thirty-six hours we find in positive cases massed colonies. A bit of culture is smeared on a slide and a gram stain used. The microscope then shows an abundance of organisms having a characteristic morphology. The entire question is one of morphology. Such simplicity is not seen in the case of other germ technique. There are doubtless not only true diphtheria bacilli which are avirulent but also spurious diphtheria bacilli. The latter should possess points of difference under cultivation, and several such methods have been in use. The authors have devised one in connection with army laboratory activities which they assert to be very simple. A special culture medium consists of horse serum and glucose, 10 parts in 100, to which is added a solution of sulphuric acid (3 c.c. of a 1/100 concentration) and 30 drops of a tincture of sunflower as indicator. This serum is coagulated by heat and should be of horizon blue color with a suggestion of green, firm and elastic. Smears are obtained and sown as usual, although the technique of the authors in reference to the exclusion of accidental flora is unusually strict. Examined at the end of twenty-four hours, the true diphtheria bacilli are seen to be present in very small pinhead isolated colonies of a reddish hue. Colonies of pseudobacilli are readily distinguished by absence of stain and in other respects. These differences are accentuated with time and are so numerous that it is hardly practicable to relate them, especially those seen under the lens but the stain of the true germ deepens with time, while the other continues colorless. Accidental germs which may have been present in the throat may take the stain but are readily excluded, if necessary, by the microscope. The authors have now examined over 3,000 specimens, and with such success that the harmless saprophyte should no longer mask as a virulent germ and lead to needless isolation, especially of wrongly suspected carriers.

Autoplasmotherapy of Grippe.—The autoplasm of a grippe patient, when injected into the patient's venous system, has a temporary favorable action which is no specific but due to the action of foreign protein. Unlike many albumins, it is quite safe for the patient. In certain cases its action seems permanent and the defervescence, etc., final.—*La Presse Médicale*

Pyotherapy in the Lymphangitis of Horses.—Belin relates that he treated 1100 cases of lymphangitis in horses with crude pus or dead cultures of the bacilli with 75 per cent of good results. Of these cases 40 were of cryptococcic and 700 of bacillary origin. He prefers to associate the crude sterilized pus with the killed cultures of bacilli.—*La Presse Médicale.*

Book Reviews.

United States Army X-Ray Manual. Authorized by the Surgeon General of the Army. Prepared under the Direction of the Division of Roentgenology. Two hundred and nineteen Illustrations. Price, $4. New York: Paul B. Hoeber, 1918.

This is a remarkably well written and compiled text-book which has been prepared under the direction of the Surgeon General of the Army to serve as a guide to roentgenologists who are doing the *x*-ray in military hospitals, and, generally speaking, as a means for instruction in military roentgenology. Perhaps the part of the book to which attention should be especially called is that devoted to the localization of foreign bodies and to a description of new apparatus. The importance of the *x*-ray in military surgery has been amply demonstrated and it is therefore eminently fitting that such a work should be issued. It is extremely well illustrated.

Essentials of Surgery. A Text-book of Surgery for Students and Graduate Nurses and for those Interested in the Care of the Sick. By Archibald Leete McDonald, M.D., Johns Hopkins University, Formerly in Charge of Department of Anatomy, University of North Dakota; Lecturer on Surgery, Nurses' Training School St. Luke's Hospital, Duluth, Minn. Forty-six Illustrations. Philadelphia: J. B. Lippincott Co.

This book is made up of notes prepared for the use of senior nurses in connection with a course on "The Principles of Surgery." The course covers the general principles of surgical diseases and the pathological changes which result. Also under separate headings, the more important surgical lesions involving special regions of the body, are considered. The book should prove of much service to nurses who are ambitious to progress in their chosen calling and should enable them to become better nurses.

Lice and Their Menace to Man. By Lieut. Ll Lloyd, R.A.M.C.(T.), Chief Entomologist in Northern Rhodesia. With a Chapter on Trench Fever by Major W. Byam, R.A.M.C. New York: Oxford University Press, American Branch, 1919.

This is a small treatise on the head, body, and crab lice written for the general reader. It presents a brief but adequate description of the natural history of these parasites and the manner in which they spread the diseases which have been determined to be associated with them. The author recounts the experimental work which has demonstrated that lice tend to leave those hosts who have fever and locate on afebrile individuals and that the excreta of the lice carry the infecting material which is introduced into the skin by means of scratches. Brief descriptions are given of typhus fever, relapsing fever, and trench fever and the particular relation of the louse to each of these diseases. Principles and methods of disinfestation are also laid down. The work, though small, is very complete and is illustrated with a few well chosen and executed drawings. It is to be hoped that the necessity for the wide dissemination of this knowledge is past, but certainly no better means could be chosen for that purpose than is presented in this book.

Intravenous Injection in Wound Shock. Being the Oliver-Sharpey Lectures Delivered Before the Royal College of Physicians in May, 1918. By W. M. Bayliss, M.A., D.Sc., F.R.S., Professor of General Physiology in University College, London; Chairman of the "Special Committee for the Investigation of Surgical Shock and Allied Conditions," Appointed by the Medical Research Committee. Price, $3.00. New York: Longmans, Green & Co., 1918.

The book contains the Oliver-Sharpey lectures given by Professor Bayliss, but amplified. The questions of the production of edema and of so-called acidosis are dealt with in detail and the lectures have been brought up to date. The work is a valuable addition to the somewhat scanty and vague literature on shell shock by an eminent physiologist and should serve to clear up some of the obscure features of the condition.

Hospital Accounting and Statistics. Fourth Edition. Compiled and Arranged by William V. S. Thome, Treasurer and Member of the Board of Managers of the Presbyterian Hospital in the City of New York, Chairman of the Executive Committee and Member of the Board of Governors of the Woman's Hospital in the State of New York, Member of the Board of Directors of the Manhattan Maternity and Dispensary. New York: E. P. Dutton & Co., 1918.

This is a useful book for those responsible for the financial management and statistics of hospitals. It shows how to make up accounts and statistics of such institutions on a uniform basis, and by following this plan not only is money saved, but the accounts and statistics are reliable and valuable for purposes of comparison.

Notes on Pathological and Operative Obstetrics. By Lyle G. McNeile, M.D., Professor of Obstetrics, College of Physicians and Surgeons, Medical Department of the University of Southern California; Supervising Obstetrician, Los Angeles Health Department; Attending Obstetrician, Los Angeles County Hospital. Los Angeles: Published by the Division of Obstetrics, College of Physicians and Surgeons, Medical Department of the University of Southern California, 1919.

This is a handy little manual describing the most widely accepted views with regard to management of the patient during pregnancy and labor, and the early recognition and treatment of the various obstetric accidents. In fact, the book contains the essentials of pathological obstetrics and seems to be admirably adapted for the use of the advanced medical student or busy practitioner.

Squibb's Atlas of the Official Drugs. By William Mansfield, A.M., Phar.D., Dean and Professor of Pharmacognosy and Botany, Union University, Department of Pharmacy, Albany, N. Y.; Late Professor of Biology and Pharmacognosy, College of Pharmacy of the City of New York, Columbia University, and Botanist and Pharmacognosist to E. R. Squibb & Sons. Price, $2.00. New York: E. R. Squibb & Sons.

In the preface it is stated that Squibb's Atlas of the Official Drugs is a complete, up-to-date, and trustworthy handbook on pharmacognosy, and a perusal of the work leaves one with the confident belief that this statement is justified. The preparation of this atlas involved years of painstaking work and the result should be commensurate with the labor expended.

Use of Factory Statistics in the Investigation of Industrial Fatigue. A Manual for Field Research. By Philip Sargent Florence, M.A. (Cambridge), Ph.D. (Columbia), Garth Fellow; Scientific Assistant, United States Public Health Service. New York: Columbia University, Longmans, Green & Co., Agents, 1918.

During the war some interesting studies with regard to industrial fatigue were made in connection with munition workers and it was found that better work and more work could be done in comparatively short hours of labor than by exerting the physical and mental faculties to the point of almost exhaustion. That is, that after a certain stage the work performed is of little use, in fact, is injurious from all standpoints. The book before us demonstrates by statistics that fatigue is harmful to the worker and conducive to an inferior output and is a record of investigations made as to industrial fatigue in a large number of factories.

Om Abdominal Reflexerne et Klinisk Bidrag til Reflexeren. Paa Grundlag av Unders ϕ kelser av 472 Kasus. By G. H. Mourad-Krohn, M.R.C.P., Lond. Summary in English. Kristiania: Steenske Bogtrykkeri, 1918.

This work by Dr. G. H. Mourad-Krohn of Christiania is based on the examination of 472 cases, the majority of which presented neurological diseases of various kinds. The occurrence and significance of the abdominal reflex in various conditions is discussed. His observations chiefly concern the pathology of the reflex and are of an interesting and valuable character.

Society Reports.

AMERICAN ASSOCIATION FOR THORACIC SURGERY.

First Annual Meeting, Held in Chicago, Ill., Monday, June 10, 1918.

THE PRESIDENT, DR. SAMUEL J. MELTZER OF NEW YORK, IN THE CHAIR.

President's Address: Thoracic Surgery.—Dr. SAMUEL J. MELTZER of New York delivered this address. (See MEDICAL RECORD, Vol. 94, No. 1, July 6, 1918.)

Review of the Evolution of Thoracic Surgery in the Past Fourteen Years.—Dr. WILLY MEYER of New York presented this communication. (See page 761.)

Major G. DEHELLY of Havre, France, said he did not wish to discuss the experimental aspect of this subject, for he was not competent to discuss the different methods of research. But he would only say a word of the work of the French in war surgery. The war surgery of the chest and pleura had been revolutionized. At the beginning of the war the surgery of the chest and pleura was abstention and it was enough to say that there was a wound of the lung. The result of this abstention was really the same as in other wounds and they lost heavily from this cause, many of their patients dying of infection of the lung and pleura. The ordinary treatment of abscess of the lung and empyema was only incision. And this incision in the treatment of infection brought inside the chest by shell and pieces of clothing, and drainage of lung was insufficient to cure the infection. Progressively it was evident that the treatment of the wounds of the lung and of the infection of the pleura ought to be preventive and to follow as early as possible the introduction of the germ. Now the treatment was to open and remove the foreign body as quickly as possible and to operate in all cases of wound of the lung and pleura, not only to remove the foreign body, but to stop the hemorrhage, to dry the pleural cavity, and then to close gently the pleura. The most important point made clear forever was to close the pleura after mechanical cleansing of the lung and of the pleural cavity. The operation accomplished was consequently the wide opening of the chest, the removal of the foreign body, the removal of the walls of the wound of the lung, as was done in the case of wounds involving the muscles or subcutaneous fat; the closure of the lung, the closure of the pleura without drainage. The result was progressively better and the speaker thought that shortly these methods would be generally applied. The treatment of a foreign body in the lung followed after a long time by inclusion, was also not specifically settled. At the beginning it was abstention. Afterwards removal of the piece of shell was effected by wide opening, suturing the wall of the chest, entering the lung, and removing the foreign body by excision. But the results were not perfectly good, and these unfortunate results were not only the immediate ones. After suture of the chest many times there appeared hernia of the lung and Major Dehelly had seen recently such a case in a man who was in charge of the examination of disabled patients; he had also seen a large number of these herniæ after extraction of a foreign body. A new treatment was that of Petit de la Villion, which consisted in removing the foreign body by means of a specially constructed forceps, the blades of which did not separate widely. This operator had done a great many of these operations with success and the speaker thought his technique was good. He did not know exactly what was to be the best, but he thought it was an improvement to be able to remove these foreign bodies without a wide opening and without the danger of subsequent hernia.

Dr. JOSEPH RANSOHOFF of Cincinnati said if we went a little further back and investigated literature we would find a report of a case of aneurysm of the aorta treated by the speaker by the insertion of a great many feet of silver wire. He read that paper on "Wiring Aneurysm" before the Surgical Section of the American Medical Association at its meeting in St. Louis. The aneurysm was wired and the patient really seemed to improve. But, as so often happens, the aneurysm advanced in another direction and this man a month or six weeks later was found dead with rupture into the pleura. After presenting this paper and the specimen Dr. Ransohoff went to Pikes Peak, and on the way met a very interesting old gentleman, to whom he was introduced. He said he had heard this paper and with difficulty refrained from opening the discussion with a motion "That the essayist be hanged by the wire he had used."

Treatment of Empyema by the Carrel-Dakin Method at the War Demonstration Hospital.—Major GEORGE A. STEWART, M.C., U. S. A., read this paper by invitation. (See MEDICAL RECORD, Vol. 94, No. 6, August 10, 1918.)

Remarks Concerning the Employment of the Dakin Solution in Cases of Empyema.—Dr. CHARLES L. SCUDDER of Boston, being unable to be present, sent a brief communication. At the Massachusetts General Hospital in Boston he said they had instituted the Carrel-Dakin treatment of wounds in a systematic fashion. Through the kindness of Dr. Stewart and others at the Rockefeller War Hospital in New York, individuals from this clinic had been permitted to visit the War Hospital and secure sufficient data with regard to the technique of the Carrel-Dakin treatment to make it possible to reproduce the methods employed there. This work had only just begun so that the number of cases that could be reported was limited. They had treated within the past month about ten cases of empyema. Because of the condition in which they found these cases, the treatment had varied somewhat. The attempt had been made to remove the accumulated fluid, to sterilize the cavity, and to secure healing of the drainage wound early. These few cases arranged themselves so far as treatment was concerned in the following four groups: (1) Drainage by suction through a punctured wound with intermittent injections of Dakin solution. (2) Rib resection, drainage, and intermittent injections of Dakin solution. (3) Rib resection at the lowest point of the cavity, a puncture at the highest point of the cavity, and introduction of Dakin solution into all tubes. (4) Drainage through puncture, insertion of tubes through punctured wound and at the highest point through punctured wound, and Dakin solution. Dr. Scudder believed that the ideal method of attempting sterilization of the cavity of an empyema was as follows: Early dependent drainage by means of resection of a rib; continuous suction of all discharges through this dependent drainage wound; a counter opening at the top of the cavity sufficiently large to receive two Carrel tubes; intermittent two-hourly instillation of Dakin solution through these two tubes; flushing of the lower part of the cavity through the drainage tube with Dakin solution, and continuous suction from below. They had been able to close two such cases, both postpneumonic, after a few days of proven sterility. These closures had been possible far earlier than could have been accomplished without the use of the Dakin solution. The speaker thought it was better to introduce the Carrel tubes from above rather than to attempt to stiffen the tubes by means of silver wire and then insert the tubes from below.

Major G. DEHELLY of Havre, France, said the treatment of the infection in the pleura was done from the beginning of this attempt to sterilize the wound. They had at this time many cases of wound of the lung and the pleura, with suppuration, and they tried to secure sterilization and they obtained about the same result, but their cases were not so well studied and their treatment was at this time not perfectly settled, and they, therefore, did not publish this first attempt. Dr. Tuffier, who had followed their work in Compiegne, published a personal work of importance in the application of their technique to the sterilization of the pleura and chest, and since that time many other French surgeons had published cases of infection in the chest and pleura cured by this method. The speaker thought that the surgical technique was of great importance. It was necessary to have drainage at the lower point of the cavity, and to distribute the fluid in every part of the wound. It was for that reason that we put in these tubes some silver wire to maintain the tube in position close to the top of the chest, and to pass the fluid every hour if necessary into the

chest. The antiseptic should be brought into contact with every part of the cavity in order to dissolve the secretion and to remove the medium of culture for the bacteria. The suggestion of Dr. Scudder to make the irrigation at the upper part of the chest was possible, but the speaker never attempted it because they had obtained very good results by their simple technique, using the opening in the lower part of the chest to introduce the tube, keeping it straight by means of silver wire. He had found it possible to obtain the sterilization more quickly by attempting to pass the fluid up to the upper part of the chest. The sterilization of streptococcic empyema was especially important because the streptococcus had now the reputation of preventing the closure of every wound, and the objection to the closure made by the surgeons in Paris was always the presence of the streptococcus in the wounds. But the speaker though this rule was not absolute. He had had the opportunity to treat many streptococcus secondary complications of typhus in Rumania, and had had a large number of cases of streptococcus infection, manifested by extensive lymphangitis, phlegmons in the abdomen, parotiditis, enlarged glands in the neck, mastoiditis, and he was always able to sterilize the wound by Carrel-Dakin treatment and to obtain secondary closure. This result, especially in an empyema, was very important because it was possible to sterilize and close the chest quickly and we now knew from our experience in war surgery that it was necessary to close all wounds, and especially wounds of the thorax, in order to permit expansion of the lung and to obliterate any cavity in the chest in which secretion might accumulate and in which it was possible for a new abscess to form. They had in one of the patients who died the opportunity to make an autopsy after the closure of the empyema. This case was very interesting because it was admitted in very bad condition. They treated the empyema by opening according to the technique described by Dr. Stewart, and during the sterilization the patient showed evidences of pericarditis. The pericardium was largely filled by secretions and the heart was in a bad condition. As soon as an approximate sterilization was effected the speaker closed the empyema by adhesive plaster without suture, except simply to close the skin wound. Three days later the patient died of pericarditis. The autopsy showed the pericardium containing two liters of fluid. The chest was closed and there was no cavity at all between the two layers of the pleura. The pleura was slightly thickened. After closure we have air in the chest, which is absorbed very quickly. We know that it is necessary to inject an inert gas in order to maintain a cavity in a normal pleura. When air is present, however, it is quickly absorbed and the lung is allowed to expand very rapidly; this, Major Dehelly said, was very important in the cure of empyema. The question of time saving in treatment by this method was also very important, because we diminished the possibility of thickening the pleura, the possibility of having scar tissue in the pleura, and the possibility of the production of a scoliosis which so often followed empyema.

Dr. KENNETH A. J. MACKENZIE of Portland, Ore., wished to express his appreciation of being a member of this august body—august because of the occupation of its presidential chair by a physiologist who had the combined qualities of a great physiologist and surgeon. In looking back over a term of practice that covered more than a quarter of a century, he could recall, without being able to give the statistics, a very gratifying termination of most of the cases of empyema that had come to him after having been subjected to different varieties of operation for relief. He could also look back with a sense of satisfaction to the measures that had been associated with the treatment of empyema in general. To speak first of the operative treatment: The operations he had performed had been chiefly of the Estlander and the Schede methods. Many of these had gone to recovery without any impairment of the physique, notwithstanding the extent and severity of the operations. He had also noted in a few instances the occurrence of double empyema. He was at one time in charge of a very large construction service in the region of the Snake River, cut off from all communication with large cities. The first epidemic of influenza that spread over the country brought to that camp, of nearly five thousand workmen, many cases of pneumonia complicated by empyema. In the number of cases that came up there were five or six cases of double empyema. In two or three of these cases Dr. Mackenzie operated on the doubly involved thorax by making simultaneous thoracotomies. Two at least recovered without any untoward results, and went on to complete recovery and returned to their normal occupations. He had not previously heard or read of similar experiences with empyema. So impressed had he always been with the mutilation and shock of the usual operation for empyema that a year or two later, at the meeting of the International Congress of Surgeons at Brussels, he presented, rather boldly he thought at the time, a paper on a method of dealing with empyema in order to avoid the shock of acute pneumothorax. He had had no cases at the time but one, which was unfortunate in its termination, and one or two experimental cases in dogs and guinea-pigs. He suggested that one might be able, for instance, to operate on the thorax at two points, withdraw the pus at one and introduce a suitable solution at another simultaneously, so that the pus would be displaced by the solution. The solution he selected was sterilized petrolatum. He had often thought that this method might be tried with advantage and without hazard. It occurred to him that one might thus fill the thorax with petrolatum and study the clinical conditions afterward, and if the temperature curve suggested that the process was still active on competent evidence, the thorax could be reattacked, the pus withdrawn, and a corresponding amount of petrolatum introduced, keeping up the maneuvre until finally the clinical evidence showed that the pus was no longer present, whereupon the petrolatum could be gradually withdrawn and the lung allowed to expand. A word or two more in regard to the cases presented by Dr. Emil Beck, which possessed so much interest and value in all their bearings. Several years ago he was operating on a case of empyema, one which had defied all treatment up to that time, and had released the lung to some slight extent, and was in the act of studying the dense membrane that invested the lung when, on nicking it with his knife, he found a line of cleavage between the lung and its adventitious covering, which he proceeded to separate, when to his great surprise the lung suddenly flared out of this incision and filled the pleural space completely. He was not familiar with Delorme's work at the time. He had, however, opportunities afterward of studying the value of his observation, and it occurred to him that it might be a good plan to use this method of treatment in some of the cases spoken of by Dr. Beck. Instead of mutilating the chest, why not divest the lung of the fetters which bound it and let it come forward to its own place? It occurred to him that Delorme's work was more honored in the breach than in the observance today. Some time ago he witnessed a surgeon attacking a thorax which contained pus, making free incision, using retractors, and releasing the pus. He himself in a case a few days before he left home, in a strictly encysted empyema, followed this method and the case had progressed favorably. It occurred to him that it was the province of this body to discuss whether one were justified in taking such radical steps, and yet it was now the rule in abdominal surgery to attack these cases in the most radical manner. What was right in the abdomen might be wrong in the thorax. It would be the province of this new society, which had been launched under such favorable auspices, to thresh out these great questions.

Dr. MACKENZIE then asked for the privilege of the floor for Major Dudley Fulton of the Base Hospital, Camp Lewis, Washington, who had a message to deliver from Camp Lewis germane to this discussion, having had extensive military experience in this branch of surgery.

Major DUDLEY FULTON, Chief of Medical Service, Base Hospital, Camp Lewis, Washington, said the basis of his remarks would be the recent observation and study of 240 cases of pneumococcus and streptococcus pneumonia and fifty-seven cases of empyema at the Base Hospital. Bacteriologically, about 50 per cent. of

the empyema cases were of the streptococcus type, 21 per cent. of the pneumococcus, and 20 per cent. of the combined pneumococcus and streptococcus. The pneumonia mortality was 13 per cent. Out of fifty-seven cases of empyema there had been thirteen deaths, with a mortality of 22.8 per cent.

In December and January empyema occurred as a *sequel* to pneumonia, as had been ordinarily encountered in civil practice. Resection of a rib and simple drainage gave the usual satisfactory surgical results. But in February, and since, the empyema developed not as a sequel to, but as a *complication* of pneumonia, which presented a clinical course, pathology, and fatality never before observed in acute respiratory infections. It was early found that the treatment of empyema associated with active pneumonia, by resection and drainage, according to the old, well-established surgical procedures, was entirely inadequate. It did not seem to modify the course of the disease in the least; either early death, prolonged, unsatisfactory convalescence, delayed recovery, or serious complications resulted.

The next phase of treatment was the delay of radical operation during active pneumonia and removal of the thin, purulent fluid from the pleural cavity by frequent aspiration. As a rule, the pleural exudate had become, during this delay, thick and purulent. As a result there was a drop in early mortality, but in the end it proved an unsatisfactory procedure since it favored fibrin formation and the formation of multiple pockets of pus, making ultimate and complete recovery uncertain. Conference with the surgical staff at this time led to the decision of establishing the continuous suction treatment. A very ingenious water-pump suction was established throughout the empyema ward, making possible continuous, simultaneous suction on all patients in the ward. With the establishment of this treatment the mortality ceased. It had been used continuously for two months past and from the mortality standpoint had proven very satisfactory, but disappointing as to ultimate results, in that cures had not resulted; the need of secondary operations was frequent and convalescence was an indefinitely prolonged affair.

The surgical service was just now beginning the use of the Carrel-Dakin solution. The method, as described by Major Murphy, was both instructive and timely, as it apparently offered a most valuable means of getting the pleural cavity sterile and successfully terminating these difficult cases. We were, however, much impressed with the value of the suction treatment in empyema associated with an active pneumonia. Our explanation of its particular value was that it maintained the normal, negative, intrathoracic pressure, which was theoretically preferable, at least, to a surgical procedure which allowed the collapse of the lung during an active pneumonia. It furthermore allowed adequate drainage early in the disease, a most important consideration. The experiences gained in the base hospital at Camp Lewis, together with that found in the literature and learned in this very interesting session this afternoon, prompted the speaker to venture the opinion that in the treatment of streptococcus empyema a safe procedure would be the use of continuous suction for a week or ten days during the active pneumonia period, to be followed by the use of Carrel-Dakin solution, according to the technique described by Major Murphy.

Dr. Samuel J. Meltzer of New York City said he would like to put two questions to Major Stewart: First, how many of the forty-four cases were caused by the *Streptococcus hemolyticus* and how were the favorable results distributed between the empyemata caused by the pneumococcus and by the streptococcus? Second, he would ask Major Stewart whether raising of the posterior end of the bed would act favorably upon a more satisfactory distribution of the Carrel-Dakin solution within the pleural cavity?

Major Stewart, in closing, said that, as to the expansion of the lung, there was a collapse of the lung at the time of operation. Following closure of the pleura, the cavity was practically obliterated in from twenty-four to forty-eight hours by expansion of the lung. This was well shown by a series of *x*-ray plates taken following closure. Expansion took place very rapidly following the use of Dakin solution, which had a solvent action on the fibrin and thus prevented adhesions. It might not be absolutely necessary to dissolve out this fibrin, but if it was gotten rid of quicker than nature could take care of it, the lung would be allowed to assume its normal condition in a much shorter period of time. They had had thirty-one cases of streptococcus infection. As to the position of the bed, they had kept the patient in whatever position was most comfortable, usually in a semi-Fowler position, which most patients seemed to prefer. As to the question of suction drainage, they had tried this on one case but were unsuccessful in bringing about sterilization. They persisted in using suction until forced to give it up on account of the condition of the patient.

What Shall Be Done with the Open Chronic Suppuration of the Chest Cavity?—Dr. Emil G. Beck of Chicago read this paper. (See page 770.)

Skin-Sliding Operation for Lung Abscess.—Dr. Emil G. Beck of Chicago said that during the past seven years he had employed a surgical procedure in these cases which was less dangerous and he believed more effective. The patient is placed in a semirecumbent posture and anesthetized. Before incising the skin a rubber catheter is introduced into the existing sinus and kept there as a guide during the first part of the operation. The skin incision differs in almost every case. It depends entirely upon the location of the abscess or empyema. Dr. Beck has devised and employed three different types of skin incisions, the Y-shape, the X-shape, and the trapdoor incision. It will be noted, he said, that each of these incisions forms one or more flaps of skin of various lengths, which are intended for implantation into the lung abscess or empyema after it has been exposed. The skin is not dissected from the underlying fat or muscle until we are ready to shift it into the abscess cavity.

From three to five ribs overlying the abscess cavity are now widely exposed, and as many are resected as seems necessary to expose the cavity to its full extent. In cases of empyema even more than five ribs may have to be resected. One should remove as much rib length as seems feasible, four to seven inches of each if possible. In cases of empyema, where the cavity usually extends into the apex, we should endeavor to resect the third rib if possible. This will facilitate the implantation of the skin flap into the dome of the pleura, and prevent the prolonged granulation of this recess which occurs when the skin flap does not cover it completely.

The ribs removed, a small incision of the thickened pleura is made along the catheter, the finger is introduced, and the cavity explored. The incision of the pleura is extended upward to the highest point, with care to cut into the lung. The cavity is exposed to ocular inspection by removing as much of the parietal pleura as possible. This will usually make the opening into the abscess cavity large enough to introduce the entire hand.

In most cases of chronic empyema the lung will be found to be retracted upward and inward. At times the apex will contain functionally normal lung. In the cases of lung abscess, however, the matter is different. The globular or multilocular cavity, with thick septa, exists, into which frequently open one or more bronchi. In one of the speaker's cases, shown at a meeting of the Western Surgical Association in 1914, seven bronchi opened into one lung abscess.

The cavity, being fully exposed, is swabbed with dry gauze and the usually smooth surface of the abscess wall sufficiently scarified, either by rubbing it roughly with gauze or even resorting to a mild curettage. This is done for the purpose of producing a favorable condition for the adhesion of the skin flap. The cavity being dry, the tips of the skin flaps are drawn into the very recesses by means of forceps. Gauze is packed tightly against them, to keep them in contact with the roughened surfaces of the abscess cavity. No suture whatever is used. The denuded surfaces from which the skin flaps were taken are then covered with sterile gauze and no attempt is made to reduce their size. At this stage, Dr. Beck said, the operation was completed, while in the Estlander a great deal of work was still necessary. The procedure should not last more than

100 minutes in the very extensive cases, and could be done in sixty minutes in the less extensive ones.

Dr. Beck then demonstrated five cases, three of lung abscess and two of empyema, which had been operated upon by the skin-sliding method just described. He dwelt on points of interest, especially on the necessity of lining the old abscess cavity by dry skin and the application of adhesive plaster for the regeneration of the skin, the application of which he demonstrated in one of the cases. He said that while he did not contend that other methods should be relegated to the scrap heap, he was working on this line and others were working on another line, and then it would be possible to compare notes and see which method would produce the best results. So far he had operated on fifteen cases and had had three deaths. Two were from general anesthesia, and he would hesitate to employ general anesthesia in the future. (One of these died from aspiration of the pus, causing suffocation.) The third patient died with brain abscess ten days after the operation. Of the remaining cases, two were operated upon only last week, one of them a month ago, and another had not yet healed. The remainder are well, except one who committed suicide two years after the operation.

Dr. Joseph Ransohoff of Cincinnati said that the empyemata which came under observation in the cantonments were entirely different from those observed in civil practice. Most of the empyemata healed promptly. They did not take five or six months to get well, and usually closed after a simple drainage operation in the course of three or four weeks. This applied to empyema in children. We must bear in mind that these empyemata were absolutely pneumococcic infections. They began with frank pneumonia; then temperature ran down, then a rise, which told us to look for an empyema. Now the empyemata which were seen in the cantonments and in some of the military hospitals were entirely different. They did not begin as pneumonias. They were almost from the beginning frankly empyemata. In the empyema we saw formerly there was no fluid in the chest cavity at the beginning; it came later. Whereas in the cantonments, in forty-eight or seventy-two hours we found a fluid distinctly septic in character. It looked as though the cases that we saw now began as empyemata, much as a septic arthritis begins in a joint, be the cause what it might. One of the difficulties encountered in the treatment of empyema was the development of pneumothorax. It was a bad thing. The patient was weakened and the family were alarmed by that whistling sound. That could be obviated by making a small opening and getting a small air space. The speaker did not use this long tube drainage into a bottle, but described in the *Journal of the American Medical Association* of April 15, 1916, in a very brief article, a method that he had found exceedingly satisfactory, a method that he had found valuable in preventing pneumothorax. He took an ordinary drainage tube, covered at one end with a soft collapsible tube. That tube was inserted through an exceedingly small opening into the pleural cavity. The opening was smaller than the tube, and the tube was forced into the pleural cavity and anchored there by means of a catgut suture. The tube was inserted and all the fluid came out, so that no pneumothorax could occur while the fluid was running, and the wound was sewed up airtight. The consequence was that when the chest expanded there was no possibility of entrance into the chest cavity itself. The apparatus of Kenyon's he had not seen at work, but could readily understand in children an apparatus like that would necessitate the child's being in one position most of the time, and it would not be possible to carry that child about, as with the ordinary drainage tube covered at one end by a collapsible rubber tube. If desired to irrigate, it was a simple matter to do so through the collapsible tube without allowing the entrance of air at all. A great deal has been said of not only getting rid of fluid, but of the necessity of dissolving fibrin on the lung. Was there necessity for dissolving the fibrin? Was there any difference in the fibrin on the infected pleura and the fibrous deposits we saw in cases of peritonitis limited to the region of the abdomen, when we left Nature to take care of itself? The speaker did not know whether there was any infectious nature, but if so, was it necessary to dissolve that out in any way or would it not take care of itself? Now with regard to the leaving of some fluid in there and allowing some of these cases to close up with pus in there still, which was, however, distinctly sterile, Dr. Ransohoff had in mind, he said, a number of cases of empyema that had gone six months or a year with pus in the chest which seemingly was sterile, but what did they find in all these cases with supposedly sterile pus? It was always a *locus minoris resistentiæ*. It was always a place in which there was a tendency to reinfection, and in some cases in which a cavity contained pus that was supposedly sterile the speaker had seen a flare up five or six years later. He did not think it very wise to leave a cavity in the chest if the cavity could by any possible means be closed. He had not seen any war surgery, but there was a very large colored population in Cincinnati; many of these men used the knife, and shotgun and stab wounds in civil life were not rare. In every one of these cases the tendency to infection was enormous. A man had a broken rib, his lung was torn. From the inside that was not going to cause an empyema. It made an enormous difference whether the air which had got into the chest cavity had been filtered through the lung or from outside. In one there was sterilization, in the other none, and these cases had a tendency to suppurate in civil life. In these cases Dr. Ransohoff always drained in the way described. He had a case not long ago in which the man had one of those crushes that crush the lung, and emphysema was extensive from the neck to the scrotum and was extending into the mediastinum. The man was blue and gasping for breath. He seemed to be *in extremis*. The thing to do was to open the chest cavity and put in one of the tubes [which the speaker exhibited], and it was simply marvelous to see how that patient recovered, and recovered without any infection of his pleura at all. He had not seen many large wounds that could not be closed. He had one which came under observation of his son, Major Ransohoff, and he had the happy idea of taking a large flap from the sheath of the rectus and tucked that into the wound, and got a complete closure. He simply stated that as something that might be of some service. In regard to chronic empyemata, he had not encountered any that he had not been finally able to close. It might take a number of operations, but they eventually closed if one kept at them. The speaker could not believe with Dr. Beck that from any scar tissue we could get new skin. One could not get the elements that go to form new skin from scar tissue. What one could do was to draw the edges in closer and nearer and making seemingly new skin. As to Delorme's operation, he was sure that those who did the Estlander or Schede operation stopped their procedure when they had removed the bony framework and cartilaginous framework of the chest wall. They did not do that essential thing of loosening the lung along its attachments—they did not do that one essential thing. He thought it was not Delorme but Fowler who did this, taking off the whole thickened pleura. It might be that many of those present never had heard of what the speaker had described as discission of the lung—discission of the pleura. It was known that the lung itself, in even the longest standing cases of empyema, was still capable of expanding; that the alveoli were there pretty much the same as they were in the lung of a child who never had breathed, and all that was necessary was to give these alveoli an opportunity of expanding. He proceeded in a case of this kind to take off the thickened pleura from the surface of a lung, which he knew was a pretty bloody operation. As soon as that incision was made the width of a knife blade of course it gaped widely. In other words, he had cut through scar tissue and that retracted. Where he made a lineal incision he saw a little blue line of lung tissue, and said to himself, if one incision would get wide like that, why would not two? The third did the same thing and the fourth did the same. If the perpendicular would go wide and show the lung substance, why would not the horizontal? He acted on this thought and had made a gridiron appearance just deep enough to divide the scar tissue, and each one of these larger islands contracted until they

were no larger than peas, and underneath the little thickened pleura left the lung expanded. (*Annals of Surgery*, April, 1906.) He would ask his hearers please to bear in mind this method of discission as an aid in helping along these cases of empyema that were so exceedingly trying.

Major DEHELLY of Havre said that his chief, Nelaton, had done exactly the same operation as that described by Dr. Ransohoff. They had tried decortication and had had some difficulty, but after having removed a number of ribs they had a perfectly good result. He did not think this observation had ever been published, but he had assisted at it when he was intern to Nelaton ten years ago. He thought it a very good operation to insure expansion of the lung. About the treatment of empyema by aspiration and washing out the chest by the bottle apparatus, they had tried once to do that and failed to obtain sterilization, and were then obliged after three weeks to reopen the chest and resort to the Carrel-Dakin treatment.

Dr. B. MERRILL RICKETTS of Cincinnati said he would like to answer Dr. Ransohoff's question as to whether there was any more necessity for getting rid of fibrinous deposits in the pleura than in abdominal work. It was with reference to the pleura, but the pleura was nothing but an extension of the peritoneum, and therefore he did not see any more reason why we should wipe or clean off one than the other.

Dr. RANSOHOFF said he would like to know when the lung did not sufficiently expand what the experience had been as to the cavity between the unexpanded lung and the chest wall—whether this cavity was filled up by fluid, by lung, or by air.

Dr. B. A. BOBB of Mitchell, S. D., said he could not claim the honor of being a member of this august body and neither was he from New York, Chicago or Portland, but from a little town of about 8000 population out in South Dakota. However, he wanted to thank Dr. Peck for the instruction he had given in his paper read at this meeting. The speaker had operated on forty-nine cases of empyema out in the little town of Mitchell, S. D., and up to this date 95 per cent. of the cases had recovered. Necessity is said to be the mother of invention, and he was forced, after operating by resecting a piece of rib and inserting a tube, to attach something to that tube to receive the drainage and keep the pressure negative in the pleural cavity, so he simply pulled off his rubber glove cut the tip of one of the fingers off and placed this glove finger over the tube and tied it on with catgut, the other end being tightly clamped with artery forceps. This forceps was released as the glove filled with pus and thus the cavity was drained very nicely.

Dr. EMIL G. BECK of Chicago said, in closing, in regard to true skin being formed over the granulating surface and in reply to Dr. Ransohoff's question, he would ask that he examine the slides and he would see that the skin grew from the edges. The microscopic specimens showed that regeneration took place the same as from skin grafts. The growth took place only from edges of true skin, and not from connective tissue. In the lung abscess of the girl who had been seen at the meeting, one noted that the entire cavity was pretty nearly covered with skin. Dr. Ransohoff was correct in stating the impossibility of forming epithelial cells from connective tissue. Epithelium would not grow from connective tissue, but skin would regenerate from skin flaps, just like other tissues, bone, nerves, etc. If he would carry out experiments on animals, as the speaker had done, he would not doubt it. In regard to drainage, the speaker had carried out the plan of drainage by the air tight tube. It depended altogether on what type of infection one had to deal with. Mild infections responded readily to simple drainage. In the case of a severe infection of the pleura, it required some modifying substance. He did not claim that it must be subnitrate of bismuth. Any substance which produced sterilization and softening of the pleura would gradually favor the reexpansion of the lung. In regard to fibrin formation in the very acute cases, he believed that if the hypochlorite solution had a tendency to dissolve the fibrin, it was an advantage, because it was likely to liberate locked-off abscesses within the pleura and thus permit the sterilization of all recesses. Post-mortems had shown that in some cases there were multiple abscesses within the pleural cavity produced by adhesions of the fibrinous exudate, and these could not be localized or drained before death. If, therefore, we were able to dissolve these adhesions and liberate the pus, the hypochlorite would be of great advantage.

Dr. WILLY MEYER of New York said he was sure that all felt very greatly indebted to Dr. Beck for having given this splendid presentation of his experience. Every one knew what it meant to deal with these cases. We all had had patients of this type under our care. We had laid the old empyema cavity open widely, completely resecting the roof formed by the chest wall, and then allowed the skin to grow in. In a few obstinate cases we had had to put a skin graft into the depth of the wound. Dr. Beck advocated the principle, not to remove the overlying portion of the chest wall, but, by means of a proper plastic technique, to allow the skin to grow in. The plan represented a new principle for the treatment of chest cavities.

Post-Operative Thoracic Drainage (Exclusive of Empyema).—Dr. NATHAN W. GREEN of New York opened this discussion. He said the number of civil duties contingent on war duties that had been placed upon him had kept him from writing any formal paper, but he had thought of a few points and had jotted them down in connection with this topic. He would try to make it as short as possible because some of his hearers had been there nearly all day and the afternoon was short. The topic for discussion was "Post-Operative Thoracic Drainage" (exclusive of empyema). Whatever he might be able to say on this subject he trusted would challenge free discussion and so we might be aided in arriving at helpful conclusions. We could be guided in our attitude toward thoracic drainage by three beacon lights: (1) logical reasoning, (2) experimental results, (3) clinical experience.

It was logical to believe the pleura required drainage if we could put our finger on contamination. It had been proved experimentally that the pleura in animals might become infected and produce a purulent exudate if it were widely exposed for the space of two hours, without further irritation. It had also been proved experimentally that it might be widely opened for a shorter time and infectious material imposed upon it and yet it would require no drainage (*Annals of Surgery*, October, 1911, p. 551). Clinical experience had shown us that the chest might be widely opened and the viscera manipulated and the wall then closed and no infection would supervene. Clinical experience in thoracic surgery was mounting up very rapidly at the present time upon the fighting front. War wounds of the chest produced operative conditions and amid unfavorable environments. We must look to some of our confreres in Europe for some very important observations upon the postoperative and posttraumatic drainage of the pleural cavity. The wonderful experience and advances reported by the French surgeons and in this meeting by Major Dehelly were adding daily to our knowledge of this subject.

Col. H. M. W. Gray, writing in the *British Medical Journal* for November 3, 1917, said: "It is very desirable to close the chest completely in every early case. I believe that by so doing the mortality will be lessened." He further stated that during one month 198 cases were operated on at certain casualty clearing stations with drainage of the pleural cavity; 99, or 50 per cent., of these died; 57 cases were closed completely and 17 died (29.8 per cent). It appeared to him, therefore, that the operation with complete closure was 20 per cent. better than the operation with drainage.

It was as Major Dehelly had remarked this morning. Many of these cases when widely opened and left in the hands of the average interne might become widely infected. One might go into a ward and turn down the sheets and the dressing would be off and the sucking wound drawing in infection. "It may be necessary to reopen the chest on account of the development of intrapleural sepsis or to remove a foreign body, but by the time this is necessary the patient has been tided over his dangerous period, and when the pleural cavity is drained there is not any more respiratory distress than after an ordinary empyema operation," said Col. Gray.

Captain J. C. H. Roberts and J. P. Craig of the R. A. M. C., in speaking of the surgical treatment of severe war wounds of the chest remarked: "No cases

were drained unless (1) the chest wall could not be closed, owing to the condition of the patient; or (2) infection of the lung or of the pleura, as distinguished from its contents, was definitely established." They further stated: "We soon overcame our scruples about completely closing up cases with a streptococcal infection, but we must admit to a more gradual conversion to the idea of closing cases with anærobic infections. This, however, we have proved to be quite a safe procedure when the precautions we have enumerated are carried out," *i.e* clean surfaces left internally. Their operative work was done preferably under local anesthesia. Of the open or sucking wounds with free air entry, of which they had 29, 5 recovered with pleura closed out of 12 operated on and the wound closed; 7 died, making a mortality of 58.3 per cent. Of 17 in which the pleura was drained 5 recovered and 12 died—a mortality of 70.5 per cent. The commonest cause of death was bronchopneumonia of the uninjured lung.

Dr. Frank J. Hathaway, writing in the *British Medical Journal* for November 3, 1917, advocated closing the pleura. All these observers agreed to close the pleura first, and that the closed pleura cases in war operations on the chest did better than those with primary drainage. Our fellow member, Dr. W. M. Boothby, writing in the Boston *Medical and Surgical Journal* of his experience on the Harvard University Service at the American Ambulance, Paris, gleaned from 21 wounds of the chest, advocated, in summarizing his observations, the avoidance of negative pressure brought about by an aspirating bottle in hemorrhage.

After three days the danger of infection exceeded that of hemorrhage. An elevation of temperature indicated the necessity of an exploratory aspiration. When the pleura had become infected, free drainage by a long thoracic opening was indicated. Now, if we were going to close up tightly all pleuræ after an intrathoracic operation, it seemed to the speaker that we must either have some certain means of knowing when disaster in the form of infection was approaching and make sure of its advent by exploratory puncture again and again, or we must do as we did in other regions, provide an easy means of escape should pus form, or, better, draw off either by a tube or by some other means the serous exudate which came first and was the precursor or concomitant of disaster. Dr. Green was fully satisfied that many cases did not do well *because they were constantly reinfected.* This must nearly always happen with the ordinary open means of short tube drainage. Some form of closed drainage with a long tube which would provide a moderate column of hydrostatic pull and prevent the suction back of contamination from the unclean outside surroundings seemed clearly indicated.

It seemed to him it was a safe procedure; it was an open pleura but it was a pleura which was ready to have the stopper drawn out of it. The drainage was potential, and if any serous or purulent exudate occurred it was ready to run down into a reservoir below and we did not have to subject the patient to repeated punctures and discomfort. These lung cases, especially in the young and in children, disliked to have needles thrust into them repeatedly to find out whether or not there was pus present. If one could place the closed drainage in the pleura it seemed to him that it was the more ideal way. The Kenyon method of introducing some such tube had been before now advocated by Dr. Meyer and seemed to fulfill these necessary requirements. In urgent cases this, coupled with some form of differential pressure which did not disturb the patient's comfort, might prove most efficacious.

Dr. Willy Meyer of New York continued the discussion. (See page 773.)

Dr. Conrad Georg, Jr., of Ann Arbor, Michigan, said he would not take very much time to make a few brief remarks on some experimental work which he had carried out on dogs, which might have some bearing on this question of drainage for intrathoracic operations. As a result of a series of experimental lung lobectomies performed upon dogs, he found that in those cases where the external wounds were closed without drainage there were more recoveries than when drainage was used. Dogs were especially susceptible to pleural infection and many of them died of empyema where drainage was used in intrathoracic operations. The technique which was employed in these operations was as follows: Care was taken to protect the pleura and lung from unnecessary traumatism during the operation, through hemostasis of the lung structure, ligation of all the bronchi, and careful approximation of the edges of the wound in the lung with stitches of black silk passed carefully through the substance of the lung. In addition to this a strip of fascia lata was sutured over the wound in the lung. The pleura and intercostal muscles were sutured with linen thread, the last suture being tied during expiration. The edges of the skin were approximated with an additional suture of linen thread. Similar surgical principles had been applied in the treatment of gunshot wounds of the lung in the war zone. It had been found best to perform these operations as soon as shock disappeared and within twelve hours after the accident. All foreign bodies were removed, the infected tissues dissected out as far as possible, large wounds of the lung sutured, and the external wound closed without drainage. About half the cases recovered with primary union of the wounds. If infection took place, the edges of the wound got moist within forty-eight hours, the wound swelled, pus formed, and the stitches had then to be removed and drainage inserted. Hathaway, in his description of the operative treatment of penetrating gunshot wounds of the chest in the British Army Medical Service, stated that the foreign bodies were removed from the lung, the hemorrhage was controlled, and large wounds of the lung were sutured. The pleural cavity was washed out with Dakin's solution or flavine, and the pleura completely closed. He claimed that the natural power of the pleura to dispose of infection was very strong. In the British Army Medical Service no cases were drained unless there was infection of the lung and pleura as distinguished from its contents. It has been shown that there were successful results from suture of the chest wall even in the presence of infection with anærobic bacilli or streptococci. Captain Carl Eggers in gunshot injuries of the lungs practised excision of all small lacerated wounds of the chest wall and suture of the openings. Where there were large defects in the chest wall which could not be sutured, the lobe of the lung was sutured to the thoracic window by means of silk without drainage. A piece of oiled silk or moist dressing was placed over the exposed lung surface and wound. He found that drains always led to secondary infection and that without them, primary union sometimes resulted.

Dr. Nathan W. Green, in closing, said that he had just a word to add and that was in regard to the drainage of the chest. I think Dr. Meyer had crystallized our duty in the following sentence: "All we use in surgery must be so perfected that it cannot do harm." He thought that statement was worthy of passing along and being kept alive. Another thing he wanted to speak of was in regard to what Dr. Ransohoff had said in discussing the treatment of the lung tissue. Dr. Green's former colleague at the City Hospital, Dr. Dawbarn, used a similar method and he performed it with the aid of a long knife, which he had made particularly for this purpose, on the back of which was a protector to keep it from cutting too deeply in the lung tissue. He reached up through the opening between the ribs and cut down in strips on the outside of the lung with the idea of dividing thickened pleura into ribbons and allowing the lung tissue to expand.

Roentgenograms of Empyema.—Dr. B. Merrill Rickets presented a series of *x*-ray pictures from cases of empyema, together with brief histories of the cases.

Pharyngeal Insufflation.—Dr. S. J. Meltzer showed some lantern slides illustrating the pharyngeal insufflation method which he had mentioned in his presidential address. On the first slide one saw an etherized and curarized dog with the thorax wide open. The pharyngeal tube was *in situ* and the insufflation was carried on by means of a foot-bellows. The second slide showed the tube removed, the animal paralyzed, the lungs completely collapsed, and the heart small and blurred, though it was still beating energetically. In the third slide the animal was in same position except for the heart, which now looked large and well defined; the heart was not beating and the right ventricle was greatly dilated. The operator was seen ready to insert the tube. The fourth slide (fifteen seconds after the third) showed the pharyngeal tube inserted, the appa-

ratus working and the lung widely distended. In the fifth slide (one hour later) the thorax was seen to be completely closed during a distension of the lung, the dog was standing up and appeared to be in a normal condition.

A Vote of Thanks to Dr. Meltzer.—Dr. WILLY MEYER of New York said he was only too happy to make this motion. All were delighted, when founding this association, that Dr. Meltzer consented to become its first president. If the speaker had been a member of the nominating committee, he said, he would have pleaded not to permit any officer of the association to leave his post during this terrible war. But the president did not agree with him, and did not put him on the nominating committee. He felt sure he was voicing the sentiments of every one present when he said that the association was pround and gratified to have it spread on its minutes, that Dr. Samuel J. Meltzer, the renowned physiologist and internist, the man who had done so much for the evolution of thoracic surgery, had been its first president. Dr. Meyer than moved a rising vote of thanks, which was seconded and unanimously carried.

THE PRESIDENT then said: "I believe that I am justified in stating that the first meeting of the American Association for Thoracic Surgery has been a great success; we have had a splendid meeting. The success of the association will grow with the growth of the understanding of its objects. I am confident that a time will come when thoracic surgery will be equal in importance to surgery of the abdomen. But, gentlemen, in order to attain this desirable aim you all must put your shoulder to the wheel. I thank you and wish you all success—either in the recuperation during your summer vacation or in the intensive war work in which you may be engaged."

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

AMBULANCE DE "L'OCEAN," published under direction of Dr. A. DEPAGE. 376 pages, illustrated. Price 14 shillings. Published by Masson et Cie., Paris, France.

THE WHOLE TRUTH ABOUT ALCOHOL. By GEORGE ELLIOT FLINT. 277 pages. Price $1.50. Published by The Macmillan Company, New York.

VEGETATIVE NEUROLOGY. By Dr. HEINRICH HIGIER OF Warsaw. 144 pages. Price $2.00. Published by the Nervous and Mental Disease Publishing Co., New York and Washington.

ANNUAL REPORT OF THE DEPARTMENT OF HEALTH OF CITY OF NEW YORK FOR YEAR 1917. 105 pages.

LA PROTHÈSE FONCTIONNELLE DES BLESSÉS DE GUERRE. By Dr. DUCROQUET. 233 pages, illustrated. Price 5 fr. Published by Masson et Cie., Paris, France.

COLLOIDS IN BIOLOGY AND MEDICINE. By Prof. H. BECHHOLD. 435 pages. Illustrated. Price, $5.00. Published by D. Van Nostrand Company, New York.

SURGICAL ASPECTS OF TYPHOID AND PARATYPHOID FEVERS. By A. E. WEBB-JOHNSON. 175 pages. Illustrated. Published by Oxford University Press, New York.

ANATOMY OF THE PERIPHERAL NERVES. By A. MELVILLE PATERSON. 149 pages. Illustrated. Published by Oxford University Press, New York.

THE EARLY TREATMENT OF WAR WOUNDS. By H. M. W. GRAY. 276 pages. Illustrated. Published by Oxford University Press, New York.

A STEREOSCOPIC ATLAS OF PLASTIC SURGERY OF THE FACE, HEAD AND NECK. By JOSEPH C. BECK, M.D., F.A.C.S. Price, $7.00. Published by the C. V. Mosby Company, St. Louis, Mo.

VITAMINES. 19 pages. Published by Frederick Stearns & Co., Detroit, Mich.

AIDS TO SURGERY. By JOSEPH CUNNING and CECIL A. JOLL. 416 pages. Price, $2.00. Published by William Wood & Co., New York.

Miscellany.

Grippe Cartoons in 1848.—It is not generally known that in some of the old pandemics of influenza in Europe the conditions which prevailed were amply visualized by the artists of the time. In the *Journal de médecine de Bordeaux* for March 10 nine cartoons from the private collection of a physician are reproduced. The sources in which these originally appeared are not stated and it is not even certain that the sketches were ever published. The first shows a pharmacy crowded with patrons of all kinds with the proprietor begging them to wait their turns. The legend is "View of a Pharmacy in January, 1848." The second cartoon shows a debtor declining to settle the bill of a caller with the excuse that he has the grippe. An officer asks his lieutenant the whereabouts of his command and receives the answer that all hands have gone to bed. An invalid bundled in an arm chair and surrounded by empty bottles is being informed by the medical men that he will be better after a few more flasks of syrup have been taken. At a play actors and audience are all sneezing. A fare is objecting to the cabby that he is driving too slowly and is informed that the horse has the grippe. A lady has her table set for forty guests, not one of whom has arrived and a page is bringing in a tray heaped with notes of excuse. The Cholera, approaching France, turns and flees at sight of the sign "Beware of the Grippe."

An Interesting Medical Diary.—Dr. VAN ZUIDE of 's Gravenhage, Holland, recently obtained access to a manuscript of unusual interest, the contents of which he describes in the *Nederlandsch Tijdschrift voor Geneeskunde* for January 18. In this book we find a record of all the confinements in the practice of a Jewish physician from 1797 to 1835. There are also data about the writer's family. The medical man's father was a man of consequence, born in 1748, by name Elias Stein. He was distinguished chiefly for his attempts to popularize the game of chess, and was instructor to the royalty of his time. He also published a book on the game in French, date 1789. His son, the doctor, Samuel Elias Stein was born in 1778, entered the University of Leyden in 1794, and graduated therefrom in medicine in 1799, with dropsy as the subject of his graduation thesis. He not only became eminent as a practitioner, but after the emancipation of the Hebrews in Holland in 1795 distinguished himself in various ways as a public man and was made a Knight of the Order of the Nederlandsch Leeuw. The names of the women confined appear to show that from the very first he practised among the Christians. When he confined a Jewish woman he made the entry in Hebrew. The total number of women confined by him was 1,842. His death took place in 1851 at the age of seventy-three. Records of confinements of his own wife are recorded from 1812 to 1821. During this period she gave birth to eight children, five daughters but one. The son, Emanuel Samuel Stein, was born in 1813, and the author adds without details that he also became a popular and successful practitioner who lived until 1895. He resided in The Hague, and his grateful patients have erected a monument to his memory. He left no male issue, and with him the male line became extinct.

MEMORY

(THE MNEMOLOGIC PHENOMENA)

IN RELATION TO INTELLIGENCE, PEDAGOGICS, AND PSYCHOPATHY.*

BY J. VICTOR HABERMAN, A.B., M.D., M.S.D.,

NEW YORK.

RECENTLY CAPTAIN, MEDICAL CORPS, U. S. A.

THE memory function is really not a function as such, but a *process* or series of phenomena, by which sense-perceptions are consciously registered and somehow imprinted on the mind. These impressions are latently retained in the form of depositions or dispositions,† being again revivable to consciousness—recallable to mind—after varying intervals of time. Three definite phenomena in this process, therefore, *impressibility* (*i.e.* the infixing phenomenon, the acquiring of depositions), *retention* and *recall* (or reproduction, *i.e.* the actualization of latent depositions to consciousness).

Impressibility.—Sense-perceptions, however, may be registered in several distinct ways. They may be accepted as such (a sound, or arrangement of sounds, or a visual image, or arrangement of images), as is the case in observational noting; or they may be accepted as symbols (as is the case with language) designating meaning—in which case the symbols are but fleetingly heeded and just barely sufficient to apprehend the idea associated. Indeed, in the latter instance, the symbols themselves are ignored—no dispositions formed—the ideas alone, and in coherent context, being recorded.

Still a third form of infixing may be differentiated, that, namely, in which the general content of the matter solely is taken up and retained. Here neither the words heard or read, nor the individual ideas, nor the particular arrangement of the presentation, are of moment to us—only the thread of thought winding through the whole. In this form of mental prehension, we do not expect to remember and recall the *text* of what is heard or read "word for word," but only the *meaning*. It is as if we abstracted the pith of the thing and stored it in mind, and when on later occasion recalling, drawing off a kind of essence of this, or when expression of it is necessary, feeding it out into our own words and amplifying with incidental, not always absolutely pertinent, details. Pedagogically, this form is referred to as *rational learning*, and the accumulated data forms our *logical memory*. This is the method of learning, according to Meumann,* employed by us in dealing with by far the greatest part of the material presented through the medium of books, magazines, conversations, lectures, scientific study, etc.

In committing to memory in the first form of infixing, the sense-perceptions as such are mentally repeated; in the second form, the ideas, idea for idea, are rehearsed; in the third, it is assumed that if once understood, the gist of the matter will be retained without repetitions, though an occasional review of it will help to strengthen the retention.

Retention.—Memory is furthermore characterized by several definite types of *retention*. In the one (*a*), we but briefly retain the matter impressed, and for the purpose of *immediate recall*. Here we only intend that it should be briefly held. In such instances, the recall or reproduction occurs before the perception has entirely faded from consciousness. (Thus, for instance, we hold a 'phone number just looked up only long enough to give it to the operator; or listen to what is said in passing conversation just long enough to understand or answer, etc.) It is really not a reproduction, Meumann states, but rather a reinforcement of the fading primary impression.† In a second (*b*), the retention is more prolonged, but nevertheless temporary—for *mediate recall*—and is not meant to be permanently held. In the third (*c*), the retention is intended to be lasting (*i.e.* our knowledge).

In mediate memory, the recall is deferred until (that is, beyond) the perceptional excitation has entirely come to an end. Thus the "memory" has

*This is the third report on The Mind and Its Examination. The first Report[2] appeared in the MEDICAL RECORD, Dec. 1, 1917; the second,[3] in the same journal, May 18, 1918.

†One speaks of *Depositions* or residua, if the matter is taken up from the physiological aspect (see [1]), or of *Dispositions* when the psychological is focused on (see [1] and [4]). Both terms, however, apply to the same thing, the memorial imprint or latent potential, which, however it be explained, we know is again actualizable to consciousness. (Cf. the *engramme* of R. Semon, also [5]).

*Our pedagogical exposition here and in other portions of this study follows Meumann's teaching, especially as given in his work on "Ökonomie und Tecknik d. Gedächtnisses," Leipzig, 1908. Our references are to Baird's excellent translation.[4]

†This is similar to James, who writes, "An object which is recollected in the proper sense of that term is one which has been absent from consciousness altogether, and now revives anew. It is brought back, recalled, fished up, so to speak, from a reservoir in which, with countless other objects, it lay buried and lost from view." (This applies to our mediate and past memory.) "But an object of primary memory"—our immediate memory—"is not thus brought back; it never was lost; its date was never cut off in consciousness from that of the immediate present moment. In fact, it comes to us as belonging to the rearward portion of the present space of time, and not to the genuine past." (See James,[5] pp. 646-7.)

been entirely out of consciousness for a time before it is again revived. But the dispositions formed in mediate memory are not meant to become *permanent*. Here it is purposed that the memory hold for just a little while. Indeed, one resolves, or *wills*, if one wishes to put it so, whether memory is to be immediate, mediate or permanent, and through this determination, the one or other disposition—as desired—takes place. Occasionally strong tonal feeling, however, will indelibilize a memory that is not meant to be held, and which, separated from the *affect*, would have only been immediate, or, at most, mediate.

These three types of reaction are quite dissimilar, and must be looked upon as separate functions of memory. Capacity in one or the other is a matter of individual endowment; and one finds *this* function strong in one person, *that* in another; or again, exceptional capacity in the one alongside of decided weakness in the other may exist in the same individual.

Association.—In the case of sense-perceptions being apprehended as symbols, that is, as ideas, they are at once *associated in mind*, linked up with other deposits of former impressions and ideas. In fact, ideas cannot be infixed without such association,* and in this sense memory may at the same time be said *to be* association.† Thus, ideas are comprehended, understood, and either passingly employed (immediate retention) for momentary orientation, current conversation, as aides to better or more thorough discernment, or as steps or premises leading to conclusions and advanced consummations of thought; or they are accepted for concrete infixing, as it were (permanent retention), and become added increment to the mass of ideas already gathered and stably organized, and which we refer to as *knowledge*.

This *association activity*‡ is a mechanism which shunts in two directions. In the one, it engages in the infixing phenomenon, determining—guiding, or more exactly, necessitated, thruogh interest, concern, motive (*i.e.* background constellation—general knowledge—and momentary constellation—associations just then in consciousness)—what shall be focused on and what glossed over and ignored. In short, it determines *attention*—and attention not only designates just the thing that shall be remembered, but inaugurates the memory-process itself, for attention must hold long enough if memory-depositions are to form. But this whole association activity, connecting, matching up, differentiating, analyzing, etc., is the mechanism through which we comprehend (and infix) the new incoming ideas. In the other direction it leads from the ideas momentarily in consciousness, backwards, over association paths into our latent stores of depositions (our knowledge), thus reviving old traces, "bringing memories to mind." In this way we "remember."

Recall.—This finally brings us to the phenomenon of *recall* (or reproduction), and we must consider the *readiness* of recall (the ability to get to the proper latent deposition when this is desired) and the *exactness* of what is recalled. In connection with the first, let me allude to a conception of Ziehen's[7] which has not been sufficiently recognized. The whole of our memories (associations) he contends may be divided into two portions, the one constantly rather active in our ideation, the other less familiar to ourselves. The former is in everyday circulation like the "current money" in a bank, easily handled, easily got to, *always ready*. The remainder of our depositions lies like the bank's reserves in deeper vaults, only to be broached on special occasions—that is, only *reproduceable* through favorable or propitious constellation. Both forms of knowledge must be considered in judging the intellectual endowment, though, other things being equal, we usually assume such individual to be more intelligent in whom easily flowing, pliant associations predominate. We refer to *esprit*, or "versatility," in such individuals. (But the "wordiness" of garrulous persons no doubt also belongs here.)

In examining normal individuals, this matter ought to be thought of in conjunction with tests of knowledge. We may, however, here say in a general way that *readiness* of recall depends upon the *frequency* with which association paths have been traversed, and likewise, the *number* of paths leading to the depositions to be awakened from the ideas momentarily in consciousness.* But tonal feeling also plays an important part, possibly *the* most important part, for the child,[8] this feeling-tone, or interest, making the memories stronger.[9] Abnormally we may come upon difficulty in finding proper associations as the forerunner of defect (Ziehen[7], p. 38.), as in epileptic deterioration. Where more outspoken, be disturbed or impossible because the memory depositions have paled out, or have been destroyed (inflammation, hemorrhage, etc.). In still other conditions, the association activity itself is normal, and can take place between old dispositions—but, *the infixing having become pathological*, no new ideas can be added, no new knowledge accumulated, hence, no association of very recent or new ideas take place.

*This has led to the use of senseless syllables or digits in certain memory tests, so as to exclude association influences. This also brings up a point invalidating many tests of logical memory, where links of the text are required (as in the news-account test). The appeal to different individuals varies greatly—and memory is strongly affected through this appeal. But most important is the fact that when such association *cannot* occur (as after apoplectic aphasia, in congenital focal weakness or aphasia [aplasia]), mental imprinting of ideas cannot occur.

†Cf. Isserlin[6], p. 144, also Ebbinghaus[10], p. 633. In this connection, but looked at from the viewpoint of recall, James[5] (p. 651) writes, "What memory goes with is . . . a very complex representation, that of the fact to be recalled *plus* its associates, the whole forming one 'object,' known in one integral pulse of consciousness and demanding probably a vastly more intricate brain-process than that on which any simple sensorial image depends." Cf. however following note.

‡*Association* of ideas must be thought of as an *activity*, not as depositions. Memory depositions are physiological and latent; they become active—are drawn into the association activity—only on becoming conscious. They are *then* psychological. In reality, therefore, memory and association are not one and the same thing, and this becomes an important point for diagnosis in pathology. From ideas momentarily in consciousness, the excitation is projected through nerve fibres (association tracts) to latent depositions elsewhere in the cortex—which depositions then become conscious (are drawn into the association activity). In pathological conditions, we may have cases in which the depositions are normal, but the *association* disturbed (thus, functionally, in hysteria, shock, inhibition—or organically through diaschisis, etc.); yet again the association may

*For a general discussion see Offner[3], p. 139 et seq. and especially Baird[4], pp. 14-33.

the disturbance (poverty) in the current-associations manifests itself clinically in thinking of a most monotonous character. Where such difficulty in reproduction of current-associations is noticed, one must diagnose between structural deterioration, pathological inhibition, perseveration and incoherence. For this purpose a brief association test will avail itself.*

The *exactness* of recall entails a somewhat different point of view. In immediate recall, an individual is able to reproduce with exactness only a very limited amount. This amount is spoken of as the "span of memory."† It is an inborn aptitude, quite small in early childhood, growing slowly with the years.‡ (Thus it is dependent on age, rather than on intelligence.) Directly one taxes the recall beyond the span normal for a given year, errors occur—even if but one extra letter, syllable or digit is demanded. Hence, we can expect exactness of recall only within the span—*and where recall is immediate* (the attention not having left the memorial matter at all).

In the matter of immediate reproduction of sentences, a few facts not generally taken account of in our testing (not at all considered in the usual Binet sentence repeating tests) must be pointed out. Directly these sentences get too long, *errors regularly occur.* These errors have been found to be of two types, senseless and sensible. (Scattering, here, also becomes a factor in evaluating these tests.) A most thorough study of this sentence test (which shall be discussed in detail when we take up the individual tests) was undertaken by Gassmann and Schmidt,[10] who found the length of sentences repeated (number of syllables) gave merely the attention span. The type of errors made, however, proved a very important matter in itself, for here it was discovered that sensible errors, as compared to senseless errors, correlated very high with intelligence.§

Let the perception *reverberation* completely fade from consciousness, that is, let the reproduction be deferred beyond "immediate recall," and mistakes as to word-for-word exactness invariably are made (when the test matter involves something heard or read). In other words, *forgetting* very rapidly sets in when recall is deferred for even the briefest time.* When the (heard or read) material contains meaning and merely the *gist* of this is to be retained, it is, however, tolerably recallable. In the case of experiences and observations, exactness of recall is normally decidedly impaired, especially in children. In fact, so usually and decidedly is this recall impaired that no two individuals will tally in the same recount, while in children any approach to accuracy is nigh impossible. Suggestibility when added, and it usually is in the young, and particularly when strong tonal feeling enters in (and this applies to adults, too), at times leads to extreme distortions of the truth.† (This comes up in connection with the tests of "report" or "reliability of memory.")

But where remembrance has become faulty in recalling something past to mind, the thing is not reproduced as a picture punctured with innumerable forgettings, for somehow the mind in the reproduction fills in the gaps with memorial interpolations, does it unconsciously and without malintention, and so subjectively patches up and tints things over.‡ "Such falsifications of memory," writes Meumann, "are products of the fusion of habitual associations." In a second form, usually where our perceptions have been of a fragmentary sort, "we always endeavor by means of the function of judgment to eke out a picture of the complete details of the experience and to combine the various components to form such a complete context as shall seem most probable." (Baird,[4] p. 8.)

This, then, gives us a bird's-eye view of the memory process, the *memory phenomena*, and makes it quite evident that a "general memory" or "memory," as usually postulated, is an untenable concept, and that to understand and differentially diagnose nor-

*Ziehen employs the following fifteen words: Woods, red, house, sickness, small, city, guilt, father, jealousy, sweet, poison, fish, wedding, to-run, death.

†That is, the greatest number of elements one can reproduce after *but one* presentation is the "memory-span." This varies, however, with the kind of elements used; it is the smallest for senseless words, then follow unconnected meaningful words, then digits, and finally connected meaningful words (see Gregor,[22] p. 89). Ebbinghaus gives as averages in the adult, 6-7 senseless syllables, 8-9 words of one syllable, 10-12 digits. But by average accomplishment he seems to mean "as many times correct as incorrect" (see Ebbinghaus[19], p. 650). Yet even here the capacity is not always a general one, but rather better or exceptional for one kind of memory (as for numbers), while it is poor for another kind. This is often exquisitely shown in mental calculation marvels, who are anything but brilliant in other fields. Finally it must be remembered that this "span" is only truthfully shown up by tests if the attention is normal (not influenced by psychopathy, reflex irritations or disease processes).

‡According to Bourdon, up to the fourteenth year; after that, very slightly or not at all. According to Ebbinghaus, the best advance is between the thirteenth and fifteenth years, after which (after full physical development) the conditions remain constant.

§Our method of applying this test is to note two things: I. The number of syllables that can be correctly given on hearing a sentence once. II. The number of errors (and how many sensible, how many senseless) made when a sentence one-half again as long as the memory-span is given. (See our test sheet, Test 2, d.)

*Forgetting begins the moment the attention lets up and veers elsewhere.

†A remarkable instance is seen in the testimony given by nine witnesses from the Appam, no two of whom agreed in their account. The *Times* had an interesting editorial on this under the title of "Varying Testimony of Eighteen Eyes," a paragraph of which deserves citation here: "Here are nine honest, intelligent men trying to tell what they saw; and no two agree. The 'inaccurate' newspapers record what thousands of persons tell, see, hear, do. The everlasting and unlimited variability of evidence, the discordance of sincere witnesses to the same fact, the practical impossibility of getting anything 'exactly straight,' are known to lawyers and must be known to laymen, and even to the superior souls that demand from newspapers an accuracy impossible in this world of appearances and errors. Let us say it frankly: Nothing can be known by the senses, nothing reported by them or by anybody with absolute accuracy. Variance often proves the honesty of the varying witnesses. There is hardly such a thing as 'a fact.' There is only fallible observation of a show or appearance, which is not the same to any two men. There is 'the invisible and inutile truth,' in theory, but how shall two mortal men agree upon it? And since it is impossible to get more than an approximation of contemporary, seen facts, past history must be a kaleidoscope of guesses, a library of fictions, many million diameters more inaccurate than the newspapers and the rest of us."

‡In this process, tonal feeling, again, plays a most important role.

malities and abnormalities of mind, these *phenomena* of memory must be individually understood and separately examined. To give them serially, they are:

1. Attention (which inaugurates the infixing process).

2. The infixing of: (*a*) sense-perceptions as such, (*b*) sense-perceptions as symbols, *i. e.* ideas; (*b*) again, is infixed either (α) word-for-word, or (β) as logical content or meaning.

3. The association attending the infixing (understanding, comprehension).

4. Retention: (*a*) for immediate recall (immediate memory); (*b*) for mediate recall (mediate memory); (*c*) for permanence (*i. e.* knowledge).

5. Recall: (*a*) readiness of same; (*b*) approximate exactness of same.

But is it necessary, one will ask, to test the *entire* process? Can we not determine an appraisal of the whole by a briefer examination? Or again, what is the significance of each in the mental endowment? Is capacity or failure in the one respectively more "intelligence-diagnostic" or "defect-diagnostic" than capacity or failure in another? And lastly, are any of these phenomena negligible for our purpose?

The answer to these questions is most important, not only for the intelligence problem itself, but for Pedagogy and Psychopathology, and indeed, to be solved, must be examined from the premise of these special domains.

Pedagogical Pertinents.—Pedagogically, one differentiates too distinctly separate types of children, one characterized by being *rapid learners*, the other *slow learners*. Every teacher is familiar with this fact in the class room. The first type of child just hears or reads a thing once or twice, and mentally has it; the other must go over and over the same thing before it sticks. In the former the infixing function is good; in the latter it is poor, *i. e.* he learns with difficulty.*

These two types also show characteristic variations in their *retention*. The rapid learner easily forgets—his memory depositions are, so to speak, not color fast, and fade.† The slow learner, though he originally must keep hard at it, finds that, once infixed, the matter is well retained. This, though not constant, is so frequently the case that the rule has been formulated in pedagogics that "he who learns rapidly also forgets rapidly." (Meumann, Höffding, etc.) But still other vital differences are noted between these types, namely, that the former *relearns* with greater ease—a considerable advantage here obtaining over the other who again relearns, where this becomes necessary, with the same drudgery and difficulty. The former also has a rapid *accommodation of attention*, and consequently an ease of adaptability; often, too, a better span of memory, besides. The latter, though hampered in speed and labored in adjustment, is, on the other hand, tenacious in his work, and, because of it, more intense, penetrating and accurate. The former, then, is bright and versatile, the latter circumscribed but thorough and dependable.

Thus we see that both these types are endowed with positive traits and shortcomings which fit each for quite different callings. One cannot offhand say one is generally superior to the other—but merely that they are different.

A third type of individual is sometimes found in whom *impressibility* and *retention* are equally good—the rapid learner who likewise has good retention. Such are the more ideal memories. These various type-characteristics are native to the individual; but it should be remembered that pedagogically (and for remedial pedagogics and psychotherapy besides) each is improvable through practice, and that a deficit in any direction can be made up with proper training.

Yet in still another connection is rapidity and slowness of learning come upon, *i. e.* good and poor impressibility—namely in the various so-called *types of ideation*, visual, acoustic and motor. Here the *visual* type of learner infixes more slowly than the *auditory* or *auditory-motor*, but is by far the more reliable.*

This does not mean, however, that visual ideation correlates higher with intelligence than other types of ideation. It appears (but there is no convincing experimental data on the point as yet) that *mixed types* show greater general endowment than the pure types (Watkin, Peiffer, Meumann), and that greater onesidedness in ideational type shows likewise a qualitative onesidedness of endowment. Thus the predominatingly auditory type is seen in the musician, the predominatingly visual in the artist. It may therefore be concluded that various types of ideation determine mental endowment qualitatively but not quantitatively, that poorer endowment may frequently be diagnosed the nearer an individual approaches such predominatingly pure type, but that the reverse cannot be maintained, namely, that such predominatingly onesidedness of type is the cause of poorer grades of endowment."

For purposes of learning, *at school*, the auditory type seems to have the advantage, for children get the larger amount of their instruction through hearing and dictation. When the ideational type is acoustic-motor, and likewise in a measure visual, the greatest advantage accrues.[12] The child, therefore, that is both a rapid learner and good retainer, and of mixed ideational type, is the most fortunately constellated for learning and the acquisition of knowledge.

The facts just stated follow the teaching of Meumann and his school, and have probably had the widest acceptance. There are those, however, who might take exception to the above, holding the subject of "ideation types" to be a somewhat moot issue, at least as to the occurrence of prior types, or as Thorndike[28] (p. 410) questions the very existence of "types" distinct enough to deserve the name. Doubtless mixed types do predominate—doubtless most individuals are "mixtures." This,

*The poor, difficult learner is in reality here the *slow-learner*. He can learn as well as the rapid learner (the one with good impressibility), but only by greater effort, by more numerous repetitions. Both are *normal* individuals. There are individuals, on the other hand, with *defective* infixing ability, as we shall see. They cannot infix at all. These are *abnormals*.

†The memory traces do not, however, entirely fade out—for memory traces are still discoverable with the "saving-in-relearning" test (to be noted further on).

*It is the predominance of visual ideation, together with labored or difficult accommodation of attention, which Meumann believes the fundamental cause underlying the characteristics determining the "slow" as against the "rapid" learner (l. c. 4, p. 183).

however, does not obviate the incidence of strong tendencies, even paramounting qualities (visualization, audition, etc.) in these mixture make-ups. They do exist—and they must be taken note of in mental examination—surely when memory is involved. Indeed, the variations observed between the results of acoustic and visual memory in Rossolimo's "profiles"[14] intimate that possibly we have not paid enough attention to this phase of the matter, especially in testing intelligence.

Briefly, I believe, one may say that the memory modality, generally, is predominating "visual." Only in the few is audition equally strong. We do, however, find decided auditory types. Meumann himself was such. Inaudi and Fertol, two famous "calculation marvels" were also of this type (see Möbius' study, "*Uber die Anlage zur Mathematik*," Leipzig, 1900. Most such "marvels" are decided visualizers, however. A very interesting pathological case of charcosy was published by Ballet. Here an individual of extremely strong visual type became aphasic, but after the aphasia cleared up found himself decidedly "auditory"—though audition before his illness was very weak. See Störring, "Psychopathology," p. 103, etc.). Possibly because of this predominating visualization, greater difficulty of tests of hearing over those of seeing have been noted by Ranschburg.

In the more modern schools the tendency exists to have the child *see* as much as possible in instruction (also to touch and feel). Thus in our schools "visualization" is probably the better asset over "audition." (For Meumann's reply to the criticism against "ideation types," see[11] p. 546 *et seq.*)

The phenomena of infixing and retaining—immediate and deferred retention—may also be examined in regard to the value of these abilities to the child in training, the advantage of one or other in the school room. (Cf. Offner,[3] p. 139, and Baird,[4] p. 140.) Here we see that the former comes into play in current conversation between teacher and child, and in interrogations, the child having to hold all questions put to it until the response has been thought out and given. Furthermore, immediate retention is involved in the getting of numbers, words, and sentences through dictation, and in the repeating of such when recounting something just read, in all mental calculations, and finally in copying, drawing, and extemporaneous translation. The phenomenon is involved in both word-for-word prescription as well as where but the general context or meaning is to be grasped. How very important, therefore, this form of retention in the mental development of the young is, is obvious.

But all this is to no profit if it cannot be retained, and though an initial purpose, scarcely comes into account as a goal for the child (Offner). Indeed, however well the child may reproduce what it hears or reads at the moment, little of this may remain even fifteen or twenty seconds later*—while it is evident enough that what is reproducible subsequent to the attention's excursion elsewhere, has left definite traces behind, and that if recall is possible several days after, the matter is fairly well imbedded in our minds and becomes useful data at our disposal. Deferred memory, then, is co-equally important with the immediate, for without immediate infixing it cannot come to pass, while immediate infixing without deferred retention is of no avail.

As to especial correlation of the one or other to *intelligence*, there is little to be found in the literature. In fact, only Whipple[13] has a definite though unsatisfying reference, saying (p. 560): "In connection with the correlation with intelligence of tests of delayed and of immediate recall, there is some evidence that correlation with the former is closer"; and again (p. 518): "Tests of capacity to recall, or to recognize after an interval of greater or less duration, would doubtless more nearly measure memory in the more exact sense of that term, but unfortunately little attention has been paid to this phase of mental testing." Indirect reference, and in the same vein, is also made by Ranschburg (see further on).

From the foregoing pedagogical consideration one at least infers the necessity of keeping the various learning types in mind (also the ideational types, though this may be less important) and of employing both infixing and retention tests—tests for immediate and deferred recall—in examining the intelligence.* If infixing tests alone are given, the passing of such might inject error into our results, for the retention may be decidedly affected and here overlooked.† Thus, if any preference is to be shown at all, this should fall to the deferred-memory tests. But the slow learner also deserves his place in the sun, his type of intelligence being no less worthy than that of the rapid learner. He shows to poorer advantage if immediate recall tests *on hearing or seeing the test matter but once* are alone employed. (This fact comes up rather definitely in connection with psychopathy.) Must we not, therefore, have tests for this type? Surely his I. Q. would prove higher in that event. Just whether mediate memory does or does not particularly correlate with intelligence cannot yet with certainty be said, but its importance in determining the diagnosis of normality or defectivity must be acknowledged.

Factors in Psychopathy.—Our examinations, of course, cannot confine themselves to normal children (as was Binet's intention), and hence both normals and abnormals must be understood so as to differentiate the two. We must borrow, as we have seen, both from psychology and from pedagogics; but we must also borrow from psychopathy, and remember it is a field of its own, and one that has considerable data to offer us and an experience that dates back ever so much farther than the pathopsychological movement of the moment. That this field has not been drawn upon to a far greater extent—was, in fact, avoided by Binet and his followers—is strange enough. But still stranger is the fact that though Binet proposed his test method for normals, and meant it to be applied to normals

*"This shows us," writes Meumann (Baird[4], p. 171), "that the rapid learner possesses in the success of his first correct recitation no guarantee of permanent retention, a fact which may constitute a serious danger for children."

*In the Binet series, as well as in Yerkes' method, tests for mediate memory are conspicuous by their absence. They are also absent in De Sanctis. Both Ziehen[15] and Rossolimo[14] (part 3, p. 251), however, consider the point very decidedly in their test series, and it is of quite special moment in Ranschburg's pair-words test and Bernstein's test of recall.

‡See under pathology, further on.

only, and in gauging intelligence and nothing else, the hysteria of the movement in America broke all bounds and at once accepted the Binet scale, not as an age-average-gradation of the normal child, but as an accurate diagnostic measuring rod for every type of abnormal whatsoever, for adult defectives, all ages of epileptics, delinquents, immoral, and even every form of psychopathic constitution besides, and this in spite of the fact that it pivots on a half dozen irregular questions, without thought of affectivity or means of spotting affective deviation from the norm.*

In the clinic, just as in pedagogics, memory, or rather its abnormalities, has been found the most important issue. Only here *forgetting* has been focused on, rather than remembrance, and one has noted divers forms, such, for instance, as in senility, paresis, the Korsakoff syndrome, the various post-apoplectic aphasias, hysterical and post-epileptic twilight-amnesias, the amnesias after head-traumas (concussion), shock, psychic traumas, fright, alcoholic, nicotine, gas and other poisonings, and occasionally after narcosis.

The mnemologic variations of these conditions have been studied chiefly in adults, and but very little in children (from the obvious reason that more adult cases of this sort are seen in the clinic). However, beside a considerable chapter on childhood-hysteria, dissociative disturbances have been pointed out in "absentminded" children, and schoolroom mistakes in such who appeared later to come down with epilepsy. More interesting, and giving a special diagnostic method of procedure, are Ranschburg's studies[16] with reaction-time in the pair-words memory test (see further on). Here he endeavored to discover differences in immediate and deferred recall between the poorly endowed but normal, and the abnormal (pathologically deficient) child. And, in fact, differences in reaction-time (of recalling the associated word) were found, and such as might prove fairly available in differential diagnosis. But considerable must still be done before we have reliable methods of separating meager intelligence endowment (normal deficiency) from stupidity,† and both from the forms of mild defect (pathological deficiency). Where mild defect occurs in a psychopathic constitution it is most difficult to decipher the condition. Normal and abnormal psychic fatigue must still be studied, and much still be done to diagnose congenital aphasic forms. In fact, these latter—like mental infantilism pointed out by De Sanctis—would surely be more frequently found if the conditions were borne in mind.

*A full discussion of this will be found in the second article of this series,[2] together with indications for the separation of intelligence abnormalities from affective deviations and psychopathic trends.

†Normal deficiency can be improved; real stupidity is an inherited qualitative condition, for which little can be done—though possibly the internal secretions may occasionally help here. A very good beginning along lines of examination in differentiating mild abnormalities was made by Rossolimo[14] (p. 296), who made a profile of 18 backward children, 53 little advancing (wenig fortschreitende) 3 with dispersed attention, or absentminded (zerstreute), 9 lazy children, and 11 profligates (lasterhafte). Out of the study of these individuals R. was able to distinguish typical types of profiles (and thus of individuals), and so speaks of "psychological types" that can be quite definitely diagnosed with the profile method.

The first thing we determine with mental tests in psychopathy is whether the difficulty manifested lies in the infixing or association process. There are cases in which the one is intact, the other invalidated, and vice versa. Thus the congenitally feebleminded may have a fair impressibility for immediate recall, occasionally even an exceptional ability—though their power of association is meager or nil. At times they are even able to infix for mediate recall, but it is impossible for them to acquire permanent memories. The acquired dementias, as in praecox or paresis, on the other hand, may still show very fair association powers—inter-associations of former earlier obtained dispositions—the severest infixing defect obtaining at the same time.[17]

To verify the general normality of the association process—that is, the understanding—I use a series of tests, the results of which may be recorded on the right upper portion of our intelligence sheet. One has the patient duplicate certain performances asked of him without, however, first showing the same, namely, to "make a fist," to "beckon with the finger," "whistle," etc. In adults, one may have the patient "strike a match," "light a cigarette," etc.* Or, best of all, one employs a routine series lending observation for cursory orientation as to the presence or absence of the various forms of aphasia and apraxia; thus:

1. Does the patient understand what is said to him? ("Make a fist," etc.)
2. Has he spontaneous speech, and is it sensible?
3. Have him repeat what you say.
4. Have him read to himself and repeat what was read.
5. Have him read aloud.
6. Have him copy something you write, draw.
7. Write from dictation.
8. Write something spontaneously.
9. Apraxia tests.

In examining the infixing ability, two types of tests are used, and one distinguishes between the infixing (and recalling) of a given number of syllables or digits *which are presented but once* (which determines the memory-span and gives an *index of the attention*), and the learning test,† in which a series of senseless syllables longer than the "memory-span" are presented. In the latter test the problem is to determine *how many presentations* are necessary before a given series of syllables (or digits) is correctly reproduced (and but once).

In the normal individual it matters not how long the series of members to be learned happens to be. We know that approximately *any* series, however long, can be learned if *repeated often enough.*

Ebbinghaus[19] (p. 650 *et seq.*) found that he could remember at an average 6 to 7 syllables on one reading, 12 syllables on 14 to 16 readings, 16 only after

*In such tests one may occasionally note the first evidence of stereotypy, perseveration, or other abnormal forms of action.

†This is the well known, possibly best known, memory test of Ebbinghaus, who was the first to undertake extended experimental studies of memory (see his "Über das Gedächtniss," 1905). This special test is spoken of as the Erlernungsmethode, *i. e.*, "learning method" or "method of complete memorization," and has been frequently employed in Psychiatry. See also his Grundzüge der Psychologie[19].

30 readings, 36 after 55 readings. Adults of 18 to 20 could recall 1½ times as many syllables or words as children of 8 to 10. Sensible connected series (as in sentences or verse) he could retain 9 to 10 times better than senseless series. In children, Binet and Henri[20] found that words in sensible connection (sentences) could be reproduced 25 per cent. better than words without connections. In giving a series of 7 *unconnected words*, they found 5 were reproduced correctly; but in sentences of 38 *connected words*, in which there were 17 groups of ideas, 15 such groups were recallable. In a sentence of 74 words, with 24 groups of ideas, 18 groups were recallable.

In the psychopathic, however, the conditions are different. Such individuals, whether child or adult, show a very rapid fatigue, and this at once reduces mental energy, attention and memory-span. Give such individual a series of syllables to learn, a series longer than their normal memory-span, and they can learn the same by repetitions, just as the normal; but whereas the normal person will reproduce any number of such syllables by increasing the repetitions, the abnormal (psychopathic) soon comes to a point beyond which he cannot advance, though he reviews the thing innumerable times. Attention has repeatedly been called to this fatigue phenomenon in both child and adult. In testing abnormals, the fact must be well borne in mind, and a procedure adopted which will mitigate this fatigue as much as possible.

The neurasthenic—he really should not come under the rubric of psychopath,* at least not in milder forms—also presents a condition to be thought of in this connection. He very frequently shows rapid mental fatigue, with or without accompanying irritability. In fact, the condition might better have been named *psychasthenia* (a term now applied to another neurosis), for it entails a cerebral functional fatigue, a rapidly waning central energy. He has difficulty in concentrating, his attention no longer "sticks." One of his most frequent complaints because of this is his failing memory. The fatigue may at times be of a special circumscribed type, such as *asthenopia*, in which vision very rapidly peters out on even the merest strain, or the condition may indeed only, or especially, be manifest in the sphere of memory, *i. e. mnemasthenia.*

True mnemasthenia, however, with more or less actual memory impairment, may occur after infections—as influenza, scarlet, typhoid, etc.—in severe anemia, in chronic insomnia, chronic cephalalgia, apraxia nasalis (especially from adenoids), chronic ear disease, chronic alcoholism, continued inordinate exertion, excitement, dissipation, etc., in which cases a chronic daily "unrecuperatedness" obtains. The same has been found after intense cramming for examinations.[21]

Again, there are such neurasthenic children bordering the psychasthenic* in whom the difficulty of concentrating is due to the fact that their attention is constantly being drawn in almost ticlike or impulsion fashion elsewhere. They are *impelled* to look here or there, to notice things about them. This occurs while they study at home, or during recitations in school, or even in conversation. They often go "wool-gathering" besides, because of a similar impellance, following now this thread, now that. Yet strange to say, they have a considerable power in repeatedly pulling up and coming back, and so in the end get their lessons done or accomplish their work, but at a great expense of energy, and often with the greatest discomfort, amounting at times to anguish. Because of this tenaciousness in "coming back," nervous children of the neurasthenic type are usually among the better rather than the poorer members of a class.

As the *attention* is so important in all tests, and one cannot truthfully appraise the native memory-span, unless the attention is intact, this factor, like that of fatigue, must also always be preliminarily considered. As just mentioned, it becomes affected through fatigue, and has therefore little vitality in the psychopathic. It is often also invalidated in the neurasthenic and psychasthenic.* But it is also transiently or chronically affected (distracted) in a whole series of conditions that have nothing to do with character changes, namely, where pain obtains, or hunger, itching, worms, nervous figitiness, aural, nasal or naso-pharyngeal irritation, ethmoid disease and nasal obstruction. Should, therefore, the test for memory-span (the usual digits-test) fall out poorly, it is imperative, before judging the child's mental ability by it, to ascertain if any of these causes for abnormal attention obtain. Finally, it should not be forgotten that the attention-span depends upon age, being meagre in the young and growing from year to year. One must therefore not tax a six-year-old with a problem involving an attention-span only normally manageable by a 9- or 10-year child.

It is because of the great difficulty at times of determining to what degree the attention is invalidated in psychopathy that the learning test has usually been preferred; and a special observation in this connection brings up two factors of importance for us. Gregor[22] noticed that there were mental patients who were able to reproduce very little *on the first hearing* (or exposure, where the tachistoscope was used), who, however, could *learn* relatively rapidly. Reversely, also, there were patients who could repeat *most of* the test series after the first exposure, but who, nevertheless, were unable to get *the whole* of the series, in spite of repetitions.† Gregor believed the first phenomenon here to depend on automatic impressibility of memory (*i.e.* our infixing ability as such), the second to the association of the individual members or links of the series. At any rate, this brings up beside the *infixing* function, a *learning* phenomenon.‡

Can we apply these findings in examining normal

*He does when he is constitutionally neurasthenic and shows character abnormalities. He is then a "neurasthenic psychopathic constitution." Most such individuals are "born neurasthenics"—are hereditarily or congenitally so. But acute or subacute nervous exhaustion after disease, strain or great effort, may show the same picture—and later clear up. Some, though, do not clear up.

*Here this term is used in Janet's sense. For a differentiation of these conditions and definitions of the terms, see the author's study on Heredity (chap. 2), MEDICAL RECORD, Feb. 24, 1917.

†Ebbinghaus[19] (p. 652) found the same thing occurring among normal individuals.

‡On using the pair-words test (see further on) Gregor found that when employing 4 pairs of one-syllable words, *with one presentation*, after three minutes, 24 per cent. of correct associates were obtained; on giving the series *twice* (instead of once), *62.5 per cent. of correct associates were obtained!*

and abnormal children? And are there correlations between the learning ability and intelligence? Let's say a child does poorly in a digits-span test, on hearing the figures pronounced once (poor attention or poor infixing?), but who does well on hearing them pronounced twice or thrice, how does such child stand in regard to intelligence endowment? Here, other things being equal, the learning test—of a series beyond the normal memory-span—may give the clew, and one may judge that individual's memory better, who can repeat the series correctly with fewest repetitions. But a series that can be standardized must yet be developed.

Still another fact was noted by Gregor. In studying the Korsakoff syndrome, he found that the memory-span of such patients was usually very brief, and that the learning of a series of syllables, as ordinarily undertaken, was here poorly accomplished, if at all possible. On the other hand, if the series, instead of being learned per "whole method" (the most rapid and propitious method in normals), was learned per "part method," such a series could not only be learned, but the re-learning time was shorter and the final retention greater. Thus in using the part method in learning and permitting repetitions, Gregor not only demonstrated that his patients with even most invalidated memories could infix series of syllables, and prose pieces and poetry, but could retain these for months.

The great importance of this discovery in its bearing on the training of defectives and in remedial pedagogics is evident. Defectives must not be taught by the "whole-method," but with small portions repeated to them over and over again. In this way much progress can be made.

And one cannot say at the moment that there are not children of meager endowment or deficient (but not defective) or special forms of abnormality, in which the memory shows this peculiar bent, narrowed memory-span showing itself by defective infixing for immediate memory, but in which tolerably fair infixing ability exists, even for mediate and permanent memory, if properly approached, this latter fact becoming evident on testing with the *learning method*, and using a part presentation—each series smaller than the average normal span—with repetitions.

But neither the infixing nor learning tests, whether well or poorly accomplished, give evidence as to the durability of the impression made—whether, in fact, the depositions formed will last much beyond the moment. To determine this, we have two test methods, the one Ziehen's *reproduction test* (l.c. 7, p. 17), the other Ebbinghaus' "saving method."

In the former a problem is offered, either an example or two in arithmetic, as Ziehen usually gives it, or a make-believe going to the store for several commodities, as I employ it in my series, after which the attention is directed to a second problem, *i.e.* the repeating of digits; following a brief lapse, the first problem must be recounted.

This is an excellent and important test, and Ziehen points out how some patients who have even good infixing ability for immediate recall, a moment after distraction have lost all that was retained. In defective children, the same is sometimes noticed. The test, in fact, often shows up mild defects in very positive fashion.* It is the best and most adaptable test for *mediate retention* that we have. It is urgent, however, that we standardize certain problems to serve for the first example.†

The Ebbinghaus "saving method," or "saving-in-relearning" (*Ersparnisverfahren*) consists of his learning test, with reapplications; *i.e.* the material learned is relearned after definite intervals—an hour, a day, a week, etc. One then ascertains how *less often* one must read the syllables on the second learning than one had to at the first learning. The fewer number of repetitions needed is the index of the retention. For instance, if at the original learning it took 20 rereadings before the line of syllables could be repeated once correctly, and after 24 hours it took 10 rereadings to again be able to repeat the line correctly, then there was a saving of 10 repetitions. Such an individual may not think he remembers a syllable of the line—and yet this test proves his latent memory of it; that is, latent traces, which can be brushed up with far less work than was originally necessary for imprinting. "Indeed," writes Ebbinghaus, "nothing is readily lost completely from mind, even if very soon one can no longer reproduce the parts." Ebbinghaus was even able to demonstrate the presence of memorial traces 31 x 24 hours after learning a series of syllables once, and he likewise notes finding traces of a poem more than 20 years after it had been learned just once.[23]

We need not here touch upon the curve, or approximate curve,‡ of normal forgetting which was mapped out by Ebbinghaus (and later altered, but on the whole substantiated, by Meumann and by Radossawljewitsch[24]) more than to say that forgetting is at first very considerable, later progressing more slowly. Even an hour after one has ceased the learning, according to Ebbinghaus, over half the work must be done again, in order to reproduce the matter correctly. After nine hours, Ebbinghaus

*In my examinations of overseas cases of post-shock, and especially post-concussion, war neuroses, I found that where memory disturbance occurred, it was usually mediate memory that was affected. In a most interesting case of post-concussion amnesia, the same was true, normal immediate memory, strongly affected mediate memory.

†In the tests for the 6-7-8th years, I use for this purpose the three commodities: Loaf of bread at 5 cents, half pound of butter at 15 cents, and some cheese for 8 cents. The Binet test of carrying out three commissions may also be used instead of the above.

‡To be accurate, we ought really not speak of this curve as "*the* curve of forgetting," for the curve mapped out here was based on the learning of nonsense-syllables only (and sensible lines, in the case of Radossawljewitsch's experiment). Using other material, somewhat different results were obtained. Thus proficiency in *addition* gained through practice was not lost as rapidly through discontinuance of practice and did not show so abrupt a fall in the forgetting curve (Kirby), while skill obtained through tossing balls or manipulating a typewriter was retained in far greater measure (Swift). So one must assume that the curve of forgetting depends upon the nature of the matter committed to mind. Commenting on this fact, Thorndike[25] (p. 254) writes: "It is possible that the secondary or so-called higher connections in the nervous system which correspond to the association of 'ideas' are fundamentally less retentive of modification produced in them by learning than are the more primary and direct neural bonds which correspond to the association of sensory situation and motor response. Knowledge may be by the nature of man's neurones less retainable than skill. Roughly, as a matter of general observation, it seems to be."

found that the loss was almost two-thirds of the work done at the outset. From then on, the forgetting went slowly. The decrease, according to Ebbinghaus, is in logarithmic progression. Thus the number of repetitions required on the following days (for 24 syllables learned with 21.5 repetitions) was 10, 5, 3 and 1. Meumann's findings, however, for the same experiment showed that forgetting was by no means as great after 24 hours. His figures are 21.6, 4, 1, and 0.7. Anent which Meumann comments, "*From this it follows that the first repetition is the prime factor in retention, and that subsequent repetitions serve only to intensify its effect. . . . In the class room, material should always be thoroughly re-learned as soon as possible after its initial acquisition, because this procedure will be found to aid retention in a most effective manner.*" Baird[4], p. 334.) The Ebbinghaus experiments, besides, bring up two most interesting facts for pedagogy: First, that material learned in parts is forgotten more readily than material learned as a single whole (so that not only for rapidity of learning, but for retention, the "whole-method" of learning is by far the best); and secondly: *If a material is memorized up to the ability of reproducing it correctly once, and then the re-readings continued, this method of learning is far less efficacious than if this rereading had been done on successive days.* Thus a series was learned in 17 repetitions, yet the repetitions continued up to 68. Another series was learned just up to the correct reproduction, also with 17 rereadings; but this series, instead of being now again reread, was first relearned on the following day (with 12), and the day after (with 8 repetitions), each time until just correctly reproduced. On the fifth day it was accomplished with 4 repetitions. Here it was found that the 68 rereadings, one after the other, were not as propitious for the later recall as 38 repetitions spread over 3 successive days. Or, in other words, 20 additional rereadings carried out on 2 succeeding days, was more economical for learning than 51 repetitions carried out directly after the first learning."[19] (p. 658.)

Instead of employing the "saving-method" in the form here described, one can combine the "learning" and "saving" method in a *test-procedure* which proves more agreeable to the test person (and far less fatiguing) than these just mentioned—tests that, by the way, are scarcely happy tasks for children—and which lends itself to wider application. This is the *pair-words test* already alluded to. The method was suggested by Ziehen,[15] possibly still earlier by Ranschburg,* as well as in a somewhat different form, with senseless syllables (the well-known Treffermethode), by Müller and Pilzecker.† I discuss and recommend it at this point especially because it is so rarely used for intelligence rating, and is scarcely mentioned in this form in our literature, and might really serve as a good test for mediate recall and finer diagnostic purposes.

The method consists of presenting, acoustically or with the tachistoscope, a series of associated words in pairs*—thus, grass—green; wall—high, etc. Directly after one presentation of the entire series (also an hour after, 24 hours after, etc.), the first word of the various pairs is given and the test-person supplies the proper associate. One notes if the associate is false or correct, or if no associate is found; one also notes (Ranschburg's method) the time taken in supplying the associate. One may likewise *learn* a series of pairs up to the point of reproducing them (immediately) correctly once (*i.e. learning method*); and one may also compute the index of retention by relearning the series on subsequent days, etc. (*i.e. saving method*). One may spot the normal "slow" and "rapid" learner with the test, try out immediate and mediate memory—that is, both infixing and retention—as well as recall. All in all, a test of considerable range.†

Ziehen used pairs composed of substantive and adjective, ten pairs. These were: Garden—large, tree—small, house—green, leaf—yellow, flower—red, table—round, room—high, bed—long, chair—low, picture—pretty:

Ranschburg gives 15 pairs in 3 groups, the first being of related substantives: House—door, steam—kettle, etc.; then 5 pairs related as coördinates, subordinates, per causality, etc.: Hand—finger, fish—water, God—creation, etc.; finally 5 pairs with clang association: Bit—bitter, etc. He also computes the average time taken for the reproduction.

Ranschburg gives his test in several ways. The best method, for the learning process, he finds to be the acoustic-motor-acoustic, in which one pronounces the pairs and the test-person likewise repeats them. Thus one is sure the words were correctly heard. The tempo is about 2 seconds a pair. One elucidates with an example or two before giving the test pairs.

One may also use 9 pairs, or several series of 9. In children or psychopathic individuals, shorter series are given to avoid fatigue. Thus it is wise to begin with 3 pairs; then try six; then nine.

In testing *infixing for immediate retention*, one gives the series once, and has it immediately repeated. (Normals will give from 75 to 100 per cent. of correct associates.)

In testing *deferred recall*, one again asks for the associates one hour and 24 hours later. In Ranschburg's tryout (24 hours deferred), normals gave a curve as follows: About 17 per cent. reproduced from 50 to 75 per cent. of correct associates, the remainder up to 80 per cent. reproduced between 75- and 100 per cent. correct associates; or all in all 80 per cent. of those tested gave between 50- and 100 per cent. of correct associates.

Where there is difficulty in infixing, one will have to give the series twice for immediate recall, and not if it is reproducible; if not, then three times, etc. This should be remembered in testing defectives and psychoses.

Ranschburg[16] (p. 109) also used this method in giving a *complete memory examination*. He employed 7 groups of tests. The first group was to test word memory (and consisted of 15 word pairs: 5 pairs of simple substantives, 5 pars of coordinates

*Ranschburg's earliest report is in Monat. f. Psych. u. Neurol. Bd. IX, 1901. But for full discussion, see[16], p. 38 et seq., also p. 105.

†The *principle* of the test seems to have been employed still earlier by Calkins (cited by Ladd and Woodworth, Psychology, p. 573).

*Hence Thorndike has most appropriately named the test that of "paired-associates."

†What is still wanting, however, is a detailed method of procedure.

or subordinates, or such associated per cause and effect, and 5 pairs of clang associates). The second group tested memory for persons: ten portraits were shown, each 3 seconds; an album containing 50 portraits was then produced and the test person picked out the pictures already seen. The third group was to test color-memory. Five colored squares (brown, yellow, green, blue, red) were displayed, these subsequently to be recognized out of 15 colors composed of 3 nuances each of the 5 shown. The fourth group tested orientation-memory (for which tests a special card mapped out with 750 squares was used. 150 of these squares were in black and irregularly scattered over the board. Five such squares were pointed out to the person examined, who was asked to remember their location —and point them out again later). The fifth consisted of 5 pairs of senselessly associated words. The sixth was to test memory for names, and here five portraits were used and each associated with (given) a name, (both Christian and family name). After a short period the portraits were shown and the name associated with each demanded. Finally, number-memory was tested with 5 word pairs, *i.e.* a street and number, or name and day of month (*i. e.* No. 59 Madison Avenue, April—the 19th).

The results of these tests on twelve normal school children of 12 years of age, and twelve educated and twelve uneducated adults, taking the groups consecutively and reckoning in percentages of correct answers, were as follows:

	I	II	III	IV	V	VI	VII
Children of 12 years..	60	70	80	40	20	30	60
Educated adults.....	67	95	80	30	40	70	80
Uneducated adults....	57	80	60	40	20	30	40

Ranschburg also attempted the task of finding differences, if possible, boundaries, in the memorial ability of the average normal and the very poorly endowed yet normal children,* and between these and the retarded in the sense of being pathologically deficient (pathologisch Schwachbefähigten)[16] (p. 46 *et seq.*). In this examination he used his pair-words method, but determined the *reaction time*, the time taken to reproduce the associate, besides noting the correct hits. This reaction time, for both immediate and 24 hours deferred memory, was computed on 110 normal children between the ages of 6 and 19, and on 37 deficient children of a Hilfsschule (sub-class school) in Budapest. The results were as follows:

As to correct hits: Immediate recall of simple logical associates was by no means poor in the pathologically deficient, even though in a good proportion of such it fell behind the average of normals and the normally deficient. Thus the average obtained by Ranschburg was about 20 per cent. smaller than in normals.* On the other hand, scattering was much greater.

Results in reproduction hits of 75—100 per cent. speak neither for a good endowment nor against a pathologically meagre endowment.

Reproductions under 50 per cent. from the school age up, argue against a good endowment.

Reproductions under 25 per cent., in the ages from 6 to 11, *but already such below 60 per cent. in ages between 12 and 19 years, argue with great probability for pathological defect.*

Very interesting was the finding that when the reproduction was again tested after 24 hours, 30 per cent. of the normally deficient showed an improvement of the reproduction. This never occurred in the pathologically deficient.

Deferred memory tests (reproduction, on merely hearing the stimulous word, being again demanded after 24 hours), contrary to the negligibleness of immediate memory tests, argued in percentages over 75 per cent., with a probability of 6.5:1 against pathologically meagre endowment. Between the ages of 12 to 19, 85 per cent. of 40 cases in normals showed reproductions above 75 per cent. The ratio here between the normals and the pathologically deficient is 8:1.

Results under 50 per cent. at ages between 6-11 speak probably from 14:1 against normality, and with probability of 8.5:1 for pathological deficiency. Between 12-19 values under 60 per cent. did not occur at all in 40 normals.

Reaction words which do not in any way associate with the stimulous words intimate, without question, of deficiency, but not exactly for pathological deficiency—although the frequency of such misassociations does not occur in the normally deficient. The reverse, however, is not true—the absolute correctness of the associations does not necessarily speak for normality.

As to reaction time: In normals, very slow reproduction time argued against an averagingly good endowment. The reverse, however, was not true; rapid reproduction did not point to especially good endowment.

The reaction time for *immediate recall* (acoustic-motor-acoustic method) in normals between 6 and 11, averaged 2 seconds (fluctuating between 1.2-3.1 seconds, never longer than 2.3 in the best endowed, nor than 3.1 in the poorest endowed). Among 40 normals at the age of 12-19 the average time was 1.4 seconds (the extremes being 1.2-1.8 seconds). The maximum time for adults, intelligent and unintelligent (only loosely estimated, however, and using the opticmotor method) was 2.4 seconds.

Thus, between the ages of 6-12 one may assume the average of 3.2 seconds in reaction time for immediate recall as the lower boundary line of normality, and the average of 1.8, at most 2 seconds between the ages of 12-19.

Longer average reaction time points with greatest probability to the pathological, while reaction time averages smaller than 1.5 (between the ages of 7-16) argues with greatest probability against pathological defect.

For 24 hours' *deferred recall* the average time in

*Such as are still permitted to attend the normal schools, but who are found generally poor. They are deficient children, but not defective. R.'s pathologically deficient are the mildest form of *defective* children, his classification being: Normal, deficient or poorly endowed normals, pathologically deficient (in reality, mildly defective), and, finally, defective. It is very difficult at times, R. points out, to get any aides either from the physical examination or the anamnesis to diagnose these deficiency cases, and only the pedagogical rating is here used at present to determine the diagnosis. (It must be admitted our word "retarded" covers a multitude of pathologies and means nothing definite.) This pair-words test with estimation of reaction time gives an additional indication.

*The abnormals were between the ages of 7-16, the normals between 6-19.

normal individuals of 6 to 12 years was 2.6 for the best endowed and 3.3 for the normal deficient (Beschränktesten). At the ages of 12-19, 3.4 seconds was the poorest score for the 40 normals tested.

Averages, therefore, greater than 3.5 *seconds argue in ages from* 6 *to* 19 *with great probability against intellectual normality, and for pathological inhibition or defect.* The average of 2 seconds noted for normals (see above) does not reason against the pathological nature of the deficiency; averages, however, shorter than 1.8 seconds, from the ages of 7 to 16, argue with great probability against such deficiency being pathological; averages of 1.6 and lower are indications for the normally well endowed.

In looking over the foregoing we must then add to what has already been noted the necessity of applying a *learning* test in our memory examination and applying it *per whole-method, as well as per part-method;* likewise *per one presentation, as well as per two or more presentations* (this being especially indicated in testing abnormals, or where abnormality is suspected). We may also compute the memory index by the *re-learning method.* All this can be conveniently accomplished with the paired-associates test, which lends itself to a time-reaction application, this latter appearing to give data that is of differential-diagnostic value. What must still be formulated is a series of pairs, graduated suitably in numbers and difficulty to apply to young and older children and to adults. The reaction-time norms estimated by Ranschburg must also still be substantiated on larger groups of individuals.

We have seen how our "learning," our acquiring and storing up of knowledge, depends on memory. And our mental development depends upon this learning and storing up of facts (*i. e.* the gathering of depositions).* Hence, the preponderant pedagogical import of memory. Even comprehension and combination would be impossible without revivable depositions. At the moment one cannot just say to what degree the individual memory phenomena and intelligence are commensurate, but we do know that there are decided correlations, and that these phenomena, if we include the attention, are the intelligence fundamentals.† Likewise, when the mind becomes diseased, or is found congenitally enfeebled, forgetting, or the inability to gather memories, are cardinal manifestations, and appear almost in typical variation in the different forms of abnormality. Thus no examination of mind, whether to determine the characteristics of normal mentality, or in differential diagnosis of the abnormal as found in deficient or defective intelligence or in psychopathy, can afford to neglect probing this memory function —can afford to neglect examining and testing it thoroughly and in terms of its individual phenomena.

The tests to be employed in this examination, and which are used in our Intelligence Examination[2]— though the precise order on our "intelligence blanks"* is not as given here—are as follows:

TESTS OF INFIXING ABILITY AND IMMEDIATE RECALL (IMMEDIATE MEMORY).

1. The immediate repeating of digits (memory-span for digits).
2. The immediate repeating of associates (paired associates).
3. The immediate repeating of sentences (memory-span for syllables).
4. The immediate repeating of a brief story (span for context or ideas).
5. The immediate carrying out of commissions.

TESTS OF (SLIGHTLY) DEFERRED RECALL (MEDIATE MEMORY).

6. Ziehen's test (recounting of purchases).
7. Retelling of above story (at end of visit).
8. Drawing of a diamond, etc., 15 seconds after exposure.

TESTS OF DEFERRED RECALL.

9. Repeating test 2 (giving only the stimulus word) 24 hours later, *and computing average reaction time.*
10. Retelling of story 24 hours later (and noting exactness, *i. e.* reliability of recall [also imagination, etc.]).
11. Redescribing picture No. 1, shown on first visit (among tests of comprehension and combination).†

(Where special emphasis is to be placed on reliability vs. unreliability of report, the *exposure test* and *suggestibility test* are also given in this group.)

TESTS FOR PERMANENT INFIXING.

These tests are taken up under *Knowledge.* (See intelligence blanks.)

LEARNING TESTS.

12. (*a*) Either a sentence one and a half times (also twice) as long as the memory span; or (*b*) 15 paired associates, are learned, for one correct recitation, the number of necessary readings noted; 24 hours after, the same is again learned, and the saving in readings noted.

PRACTICAL POINTS IN THE TREATMENT OF FEVER.

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

ONLY two days ago, word came over the telephone from a former patient of mine that the physician called in to attend him had pronounced the medicine he had taken was not strong enough to rid him of the fever from which he was suffering. At the time influenza was suspected, but not affirmed positively. The medicine the patient had taken was the salicylate of ammonium, to be taken in moderate doses frequently. For this medicine the attending physician promptly substituted a mixture of aspirin and pyramidon in quite frequent doses.

As soon as I learned what the doctor had prescribed I had a sense of sorrow, and this feeling arose simply because I do not believe in either of these remedies, and at times know they will do harm rather than be useful. Of course, we know how popular aspirin has been in later years among practitioners to lessen temperature and to diminish pains. Too frequently it is given when the diagnosis of the disease is very doubtful.

While at times it certainly seems to be useful in lessening pains and fever, there are occasions when the patient, instead of being benefited, is made decidedly worse. It is not uncommon to have chilly feelings, sweating, faintness, and even a skin eruption, quickly follow its taking. Personally, I have no experience with the newer pyramidon, which has very recently found favor with some physicians, as an analgesic and antipyretic. It is a modification of antipyrin chemically, but is said to have more prolonged, though somewhat similar effects. But why use frequently two such drugs of complicated chemical formula, and both, to our regret, the products derived from phenol? Formerly, when the Germans were in high but really undeserved great repute with us, everything that came from their laboratories received numberless encomiums. It was simply the far-sighted, sensible, and experienced physicians who combated their wide use, because they saw and recognized their evil effects almost daily. Now, I would not banish the use of some of these drugs—notably phenacetin and antipyrin—but I would limit their use very much, and only give them in very moderate doses and when there were clear-cut indications for them. Undoubtedly, when fever is high, and when with the fever there are much pain, discomfort, restlessness, a moderate dose of phenacetin, occasionally given, will lessen these symptoms markedly, and not do harm, so far as we can judge, in many instances. I fail, however, to observe that it does better work, or as innocently, as sweet spirit of nitre and spirit of mindererus, singly or combined.

Practically one reason why the newer drugs are prescribed and the older ones thrown aside is because the patient or friends not seldom read the physician's prescription, and if they find it at all antiquated in their judgment they do not believe in its utility because it is too commonplace, and something to be prescribed as an old woman's remedy, rather than that of a wide-awake and progressive physician. But let us consider for a moment what evils result from coal-tar medication, with some of their known effects, when we must acknowledge that fever is a symptom and not a disease. This symptom may arise from a variety of causes. Also it may be pronounced, serious, or very slight. If the cause be known, or probable, and the fever be light, or moderate, it is surely wisdom not to attempt to break it up ill-advisedly.

If it be very high and threatening, then, although we may not know at once the cause of it, we are justified in trying to lower it by any suitable remedy which will accomplish the object and not be too prejudicial to the patient. To what extent fever is evidence that nature is battling in our cause is not yet known positively, but we do know now, or at least we believe, that useful and numerous phagocytes are present with a high leucocyte count and also a high temperature, while on the other hand, with a low leucocyte count and a low temperature the situation of the patient may be very serious, not to say imminent. Thus it is, as we know, in lobar pneumonia, and in less degree a few other acute diseases.

During many years, but now fortunately far less, cold tubbing was insisted upon, especially in typhoid frever, when the temperature ranged high and when the coal-tar products, even in large doses, produced little or no effect in lowering the temperature for any length of time. Properly given, they were thought to be very valuable and to stimulate and invigorate the patient. To-day, thanks to a wiser appreciation of their drawbacks, they are not so

much in vogue, and to nervous patients, especially women, and during the night, are rarely given, even in well appointed hospitals. It was already found how onerous and troublesome they were, and in private practice, except among the wealthy, they could not be regularly and properly given, owing to the necessity of having three or four competent nurses, and, of course, a movable bathtub and much skill and care in their administration.

At present, we have again recurred to frequent sponges with cold water, to which we add a proportion of alcohol or vinegar. It promotes the comfort and well being of the patient and diminishes the temperature in a rational degree, quite as well as the more radical or drastic doing of the cold tub. Locally, cold applications are used in fever to lessen pain when present, but also to lessen fever.

I fail to consider this good practice, and am and have been more inclined for several years to make use of warmth rather than cold to the chest or to the abdomen. It makes a far stronger appeal to me, in that it promotes circulation in or near the inflamed parts, and does not check or throttle it when it is most required to abort or decrease inflammatory conditions. A warm turpentine stupe, or even a flaxseed poultice, has been immeasurably better, in my belief, than cold-water compresses or an ice bag. The latter in pneumonia hasten a fatal termination, and in appendicitis often make certain an operation which would have been avoided if warm applications had been persistently used.

42 West Thirty-seventh Street.

PERISINUS AND EPIDURAL MASTOID ABSCESS SUBSEQUENT TO INFLUENZA.

REPORT OF FIVE CASES.

By HUGH B. BLACKWELL, M.D.,

NEW YORK.

SENIOR ASSISTANT AURAL SURGEON, N. Y. EYE AND EAR INFIRMARY.

The following cases of mastoid infection subsequent to influenza occurred recently. They present some unusual features and suggest a phase of the present epidemic heretofore comparatively unnoticed. In common all of these patients were young adults, and each exhibited evidences of a postaural subperiosteal inflammation. In addition the operation disclosed in each patient the presence of a large perisinus or epidural mastoid abscess.

In four instances the operations were performed upon the service of Dr. Robert Lewis at the New York Eye and Ear Infirmary.

Case I.—Male. Six weeks prior to operation, while convalescing from influenza, an earache suddenly developed and continued for twenty-four hours when the drum ruptured spontaneously. The ear then discharged profusely until admission to the hospital. Three days prior to admission the tissues behind the ear began to swell. Aural examination just before operation showed marked postaural edema and redness, with slight mastoid tenderness and profuse fluctuating discharge, associated with sagging of the posterior superior wall of the external auditory canal. Temperature 100 deg. F. An *x*-ray plate by Dr. Dixon revealed a dark area in front of the sinus, suggestive of a perisinus abscess.

Operation: The mastoid bone was found to be broken down and filled with granulations and pus, smears of which showed streptococci. On removing the mastoid cortex a large perisinus abscess was disclosed extending along the anterior and external face of the vertical sinus for a distance of three-quarters of an inch. The patient's recovery was uneventful.

Case II.—Female. Three months before operation the patient had suffered from influenza and pneumonia. At that time there was some subjective disturbance in the affected ear. Owing to the fact that it soon ceased, no aural examination was made. Several weeks later an abscess developed in the lung of the left side, which was successfully drained by rib resection in the mid-auxiliary line. The patient insisted that following her initial disturbance she had suffered no aural pain nor had she noticed any discharge until myringotomy was performed on admission to hospital. On the day prior to admission she first observed swelling behind the ear. Aural examination before operation showed slight postaural swelling and edema, hardly if any tenderness, and a scanty discharge, smears of which showed staphylococci. Temperature 100.4 deg. F.

Operation:—The mastoid was found to be completely disintegrated, filled with granulation tissue and pus, smears of which disclosed the presence of *Streptococcus capsulatus*. A well developed perisinus abscess was revealed, beginning at the knee and extending downward for a distance of about one inch. The vein was partially collapsed and very dark in appearance. The operation was concluded and the patient made an uneventful recovery.

Case III.—Male. Five weeks before operation, while convalescing from influenza, an earache developed which was allowed to continue for four days before a myringotomy was performed. The ear discharged more or less freely for the following two weeks when a second myringotomy was done. About this time the patient developed symptoms of a mild attack of scarlet fever. His temperature was taken at regular intervals for five weeks prior to operation and at no time did it rise above 101 deg. F. A swelling behind the ear was noted several days before admission. Aural examination showed a marked postaural infiltration with redness and edema of the soft parts. A profuse, fluctuating, purulent aural discharge was noted but little or no mastoid tenderness. There was marked sagging of the posterior superior wall of the external auditory canal.

Operation: A large perforation was found in the mastoid cortex over the antrum region. The bone itself was completely broken down and disintegrated. After exenterating the subcortical cells, a large epidural abscess was discovered on the under surface of the dura covering the temporosphenoidal lobe. The epidural inflammation was localized and confined to the floor of the middle fossa. Neither the sinus nor posterior fossa was involved. The patient's recovery was uneventful.

Case IV.—Male. There was a history of influenza and pneumonia two months previously. While convalescing from this attack an earache developed and continued intermittently for two weeks, when the drum ruptured spontaneously. A swelling had been noticed behind the ear for the past two or three days. Aural examination just prior to operation showed swelling and edema of the soft parts behind the ear with slight mastoid tenderness and scanty discharge from the canal. Temperature 99.4 deg. F.

Operation: Revealed a broken down mastoid filled with pus and granulations. On removing the subcortical cells a well developed perisinus abscess, located at the lower extremity of the vertical sinus, about three-quarters of an inch long was found. The sinus was very dark in appearance, covered with granulations and partially collapsed. The operation was concluded and the patient's subsequent recovery was uneventful.

Case V.—Male. Five months previously, while he was convalescing from influenza and pneumonia, the patient's left ear suddenly and without warning began to discharge. There was no previous earache; the discharge continued until he came to the hospital. Three days prior to admission the tissues behind the left ear began to swell. Aural examination at this time showed edema and redness of the tissues over the left mastoid, slight tenderness, profuse fluctuating discharge from the canal, and marked collapse of the posterior canal wall. Temperature 98.6° F.

Operation: On removing the mastoid cortex and subcortical cells a large perisinus abscess was located lying over the vertical sinus and about three-quarters of an inch in length. Smears from the mastoid pus showed the presence of streptococci. The operation was concluded and the patient's recovery was uneventful.

Conclusions.—1. It is surprising to note the comparatively small number of serious cases of mastoid suppuration that have heretofore complicated influenza, when we consider the wide prevalence of the epidemic, its virulent character, and the proximate relation between the chief site of infection and the mastoid cells.

2. In cases II and V the latent manner of their development suggests the possibility of the presence of an unsuspected perisinus or epidural mastoid abscess in other postinfluenzal patients with aural disease.

3. The importance of otological examination is clearly indicated by the histories of these patients, not only when an earache is present, but in all cases of subjective aural disturbances following influenza.

4. Finally, the writer wishes to emphasize the importance, when operating upon these patients, of leaving undisturbed protective granulations overlying the sinus or brain. All macroscopical evidences of diseased bony mastoid structure should be removed. In addition to the usual technique of the simple mastoid operation, he believes in gentle curettement of the epitympanum without, of course, disturbing or dislocating the ossicular chain. He has practised this procedure for a number of years, when performing the simple mastoid operation, with very satisfactory results.

A CASE OF VIOLENT REACTION FOLLOWING ANTIGONOCOCCUS VACCINE.

By LUCIUS FELIX HERZ, Ph.B., M.D.,

NEW YORK.

FIRST LIEUTENANT U. S. O. R. CORPS,

ASSISTANT SURGEON, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, ASSISTANT UROLOGIST WEST SIDE CLINIC.

M. K., a large, well-built policeman, came to my office in December, 1916, with an apparently mild attack of gonorrheal urethritis, of one day's duration. He gave a history of two previous attacks, the last one having been posterior.

Examination revealed a slight purulent discharge which microscopically showed a few pus cells, and a very few gonococci. The two-glass test showed both glasses to be clear, the first containing a few shreds.

Treatment consisted of daily irrigations of potassium permanganate, anteriorly, with a Janet syringe, starting with a strength of 1-5000, and gradually working up to a strength of 1-500. (At that time, the writer was using this form of irrigation as a routine, but later has abandoned it in favor of 1-300 protargol.) The patient was told, also, to use hand injections of ¼ per cent. protargol at home, but refused to do this as he was a married man and had acquired an extramarital venereal disease.

As the patient still had a discharge showing gonococci at the end of five weeks, and the prostatic findings were practically negative, it was considered that he either had an excessively virulent strain of gonococci, or a markedly lowered resistance, and it was therefore deemed advisable to try vaccines with the hope of stimulating antibody formation.

An initial dose of 50,000,000 mixed gonococcus vaccine was given. No reaction followed this. Two days later an injection of 100,000,000 of the same vaccine was given. The patient reappeared in three days, he having lived too far away to have consulted me sooner. He showed a marked cellulitis of the arm in which the injection had been given—redness, swelling, heat, and tenderness all being present. He also stated that he had had violent systemic symptoms, as characterized by headache, dizziness, and high temperature, compelling him to give up work and go to bed for a day. The arm cleared up under wet dressings of boric acid, and never reached the stage of suppuration. Vaccine treatment was abandoned.

The gonorrheal infection cleared up promptly upon using irrigations of 1-300 protargol in the office, and by using hand injections of ¼ per cent. protargol at home.

I corresponded with the manufacturers of this biological product concerning this case, and they were much surprised at my report. They stated that they had marketed several thousand packages of this same strain of vaccine without any untoward reports. They also stated that many physicians had employed 500,000,000 instead of 50,000,000 as their initial dose.

My only explanation of the violent reaction produced in this case is that the patient was unduly sensitive to this type of vaccine. Either his resistance was much below par, with absence of antibodies, or, what is more probable, his system was unduly sensitive to the endotoxins of this particular type of vaccine. This is all the more probable, as antigonococcus vaccines are practically autolysins, the bacteria disintegrating very rapidly in solution, and leaving their endotoxins in their place. A reaction is hence more likely to occur than if vaccines of the more stable pyogenic organisms be given.

251 West Forty-fifth Street.

Medicolegal Notes.

Insurance Policies—Questions as to Health.—A question in an application for life insurance "Have you consulted or been under the care of a physician any time within the past ten years?" was answered "No." In an action on the policy it was held that sunburn resulting in peeling of the skin was not an illness. Illness, it was said, "means something more than a temporary indisposition, slight and trivial in its nature, and which does not really affect the soundness of the system, substantially impair the health, materially weaken the vigor of the constitution, or seriously derange the vital functions." Some authorities hold, however, that a general statement as to consultation with a physician is breached though the consultation is for a trivial ailment or injury, leaving no permanent results and not affecting in any way the risk.—The Homesteaders v. Stapp, Texas Civil Appeals, 205 S. W. 743.

Fees for Services—Statute of Limitations.—In an action by a physician for professional services in which the defense was payment and the statute of limitations, the plaintiff testified on cross-examination that he made his last visit on May 22, 1911, more than six years prior to the beginning of the action, the summons in which was dated October 10, 1917. It was conceded that the defendant was entitled to a credit of $190 on payments made to the plaintiff, and the latter relied on one or more of these payments as removing the bar of the statute. To establish the necessary facts in that regard the burden was on the plaintiff, and there must be items on both sides other than cash payments to make New York Code Civ. Proc. § 386, relating to accrual of cause of action on current accounts, applicable; but the proofs did not show that any payment was made within six years of the beginning of the action. Judgment for the plaintiff was therefore reversed.—Crump v. Sefton, 172 N. Y. Supp. 338.

Medical and Surgical Lessons of the War.

REHABILITATION IN CANADA.

By Lt.-Col. J. L. BIGGAR, C.A.M.C.,

OTTAWA, CANADA.

ASSISTANT MEDICAL ADVISER, BOARD OF PENSION COMMISSIONERS FOR CANADA.

The war found the allied nations ill-prepared for the rehabilitation of large numbers of citizens disabled by their service in the field. Few, if any, organizations existed for attention to the social needs of men suffering from physical disabilities. It was but beginning to dawn on those most interested in social-service that the provision of after care of an economic nature for those who had been maimed was essential to the well-being of society.

The principle upon which the necessity for this care is based and the justification for all the expenditure it involves is the fact, at last receiving the acceptance its truth long ago warranted, that the productive independent citizen is a genuine asset and the unproductive dependent is a definite expense to the community.

The extent of the responsibility of the State in this direction has now been generally recognized. This responsibility is greater than that of the private employer who is thought to have fulfilled his duty by the payment of a monetary compensation to those disabled in his service. The State in whose employ war disabilities occur must for its own sake however undertake in addition to restore to the utmost possible extent the economic independence of those citizens whose disabilities prevent their return to those employments in which their individual social tasks had been prevously fulfilled.

When this was first undertaken, there was revealed the paucity of the available information regarding the numerous phases of the problem. What employment can be found men with only one arm? Who can be found to instruct such men in those occupations still open to them? How best can this instruction be provided? These were a few of the questions demanding immediate and practical answers.

It was immediately realized, however, that before such questions could be applied to an individual case certain other measures must have been carried to a successful conclusion. These measures were of three allied kinds. First, the disabling condition must have been brought to its irreducible minimum by the exercise of the best medical and surgical skill; secondly, the restoration of the functions of injured parts must have been carried out to the utmost; and, thirdly, artificial appliances of the best possible types must have been provided for those who would be thereby rendered more capable of independence. These were the matters which in Canada presented themselves first for attention. It would be best to begin by describing the steps by which this attention was provided.

Medical Care of the Disabled.—When disabled soldiers began in 1915 to return to Canada, the old pre-war military hospital accommodation was found to be insufficient. It was also found unsatisfactory to treat them in the same hospital wards as men admitted for temporary ailments during their period of training before going overseas. There was established therefore, a Military Hospitals Commission under the control of which all returned disabled men were taken. This commission obtained possession of hospitals and other suitable buildings throughout Canada and erected others where satisfactory accommodation could not be obtained. These were staffed with doctors, nurses, and orderlies, and the hospitalization of the returned soldier was begun upon a broad and comprehensive scale.

It is easy to be wise after the event and to criticise to-day the extent of the medical examination of men who volunteered in the earlier days of the war. In those days the medical officer who refused to accept, despite his protestations, the would-be recruit on the ground of physical unfitness was condemned by the rejected to everlasting flame in no uncertain tone. The rush to the colors in 1914 and 1915, was so great that the formation of units was authorized as rapidly as possible. Approximately two-thirds of the Canadians who have seen service were enlisted in the first two years of the war.

In this rush it was inevitable that men were accepted who should never have been allowed into the army. Their eagerness to serve carried them far but could not enable them to overcome the definite handicap of constitutional weakness. Before long they had to be returned to Canada for discharge. Among them might be found examples of many forms of the ills to which flesh is heir. These cases, with the addition of men wounded or gassed in the first battles in which the Canadian soldiers were engaged, formed the first patients with whom the Military Hospitals Commission had to deal.

The insane were segregated in special hospitals; the tubercular were admitted to sanatoria, some of which were enlarged for their accommodation; and the orthopedic cases were concentrated for the most part in a special orthopedic center situated in Toronto. These hospitals were staffed with the best medical talent available in Canada and untiring eagerness and ingenuity were displayed in the application and elaboration of medical and surgical science to the exigencies of the situation.

In this way was begun the application of the measures above outlined. The cases of war-neuroses caused at the first some confusion. The differentiation, now daily becoming more and more emphasized, between the organic and the functional nervous diseases was then little understood. It demanded the most careful study. The sanatorium treatment of phthisis—the efficiency of which is thoroughly recognized—for the willing civilian needed some psychologic adjustment, which has been provided by the introduction of vocation training, for the soldier whose main desire usually was to get back to civilian life in which he was confident that all would be well with him. Orthopedic surgery which in pre-war days had been chiefly applied to children and the sufferers from congenital malformations needed an immense enlargement of scope to deal satisfactorily with the large numbers of patients requiring treatment. In spite of all difficulties the equipment and personnel of peaceful days were adjusted to the new necessities, and

a foundation was laid, the excellence of which subsequent progress has proved.

Lately the Military Hospitals Commission has been absorbed by a new Government department, known as the Department of Soldiers' Civil Reestablishment. The work has suffered no intermission; the staff has not been in any material respect modified. The arrangements made for the patients have been continued. Additional activities have, however, become of increasing importance and it has been seen that by uniting these under a single control, the greatest degree of effectiveness would be secured.

The closest cooperation exists between this civilian department and the military organization. Soldiers who should recover from their ailments or injuries in a reasonably short time remain on the military strength and are treated as soldier patients. Those who are likely to require a prolonged period of treatment are discharged from the army and are taken on the strength of the civilian Government department by which their treatment is continued so long as it is required. The vocational training staff of the department is represented in all military hospitals and in these the preliminary steps in training, more fully described below, are taken.

The reason for this division of the task of physical restoration is to be found in the fact, observed a long time ago, that the undue prolongation of existence under a purely military regime, with its insistence upon discipline and its reduction of self-reliance and independence of spirit, increases the difficulties of the readjustment of the individual to civilian conditions of life. The effect of discharge from the army and of treatment in a civilian institution by a civilian doctor engenders an atmosphere and encourages an attitude of mind the reverse of those inevitable under military conditions. Self-reliance and self-dependence are cultivated; appreciation of the necessity for individual effort is increased; and the effects of that self-abnegation essential in a military formation are reversed.

Another feature which deserves emphasis is the arrangement made for the treatment of men who suffer a recurrence of the disease or injury on account of which they have been released from the service. Every ex-soldier in this category is taken for treatment on the strength of the Department and is provided with free hospital accommodation and the best medical and surgical skill. In addition he is given an allowance approximately equal to the pay which he received in the army. This privilege is not limited in time. No matter how long a period may have elapsed since the man was discharged, he is entitled to the benefits of this arrangement.

Undoubtedly the door has been opened for a certain amount of abuse because it is not possible always in the case of urgent illness for the local departmental medical officer to determine whether or not the illness is a recurrence of one originating on service. The advantages of the arrangement, however, so far outweigh this slight disadvantage as to make the measure one of immense benefit to the returned man.

Function Training.—The very numbers of the disabled men have impressed upon the medical world a therapeutic feature which had earlier been somewhat neglected. Heretofore the physiological cure of injuries and diseases had satisfied the ordinary professional demands. A fresh impetus was required to emphasize the necessity of carrying treatment a step further and of providing in each individual case the greatest possible restoration of function. The French who had been the first to realize the necessity for organized effort towards the rehabilitation of the disabled soldier and had established training centers for cripples soon after the outbreak of the war, also led the van in regard to this department of scientific restoration.

Professor Amar with his adaptations of the Swedish muscle-training apparatus set the pace for the investigation of scientific possibilities in this direction. Professor Tait McKenzie in America and Lt.-Col. Wilson and Professor Bott, among others in Canada, have developed this form of treatment to a very high degree of usefulness and efficiency.

Most of the original mechanical appliances were operated by motive power resulting therefore in the passive movement only of the injured part. Later it was found that active movements were more beneficial and the machines were altered to provide for this. Finally it was observed that when the patient could see by an indicator the amount of his daily progress a further advantage was gained. So the machines were equipped with various indicating devices by means of which the extent of the movement was shown.

These machines have reached a high state of efficiency at Hart House, the orthopedic center in Toronto, where a set has been elaborated by which every group of muscles can be exercised. These have been furnished with a brake apparatus designed by Professor Bott by which the degree of resistance may be gradually raised, and with an indicator which shows the extent of the movement. The progress of each case can thus be recorded daily and a marked stimulus to effort is thereby supplied.

There have been added to these mechanical appliances many forms of games, most of them of a competitive nature. Among these badminton, billiards and indoor bowling take a high place in the training of those who have lost the full use of their arms, while a form of football played with a tethered ball and another game requiring accurate equilibrium for success have been found most useful for those whose loss of function has been in the lower extremities.

Indeed it may be said that massage, physiotherapy, electrotherapy and the many kinds of function training together with therapeutic trade teaching are, as the result of the concentration of medical skill upon the treatment of the innumerable men injured in the war, at last obtaining the recognition which their importance as scientific therapeutic measures warrants in diseases or injuries resulting in loss of function.

This form of treatment has not only proved of immense benefit, but also has incidentally corroborated certain ideas of the psychologist's, formerly conceded only a theoretic value. It has been proved to the satisfaction of many observers that those forms of training are often the most effective in which the neuromuscular effort is rendered more

or less sub-conscious by the interest taken by the patient in its results. Thus the playing of a stroke at billiards when the cue-butt is manipulated by an artificial attachment to an arm stump has been, speaking generally, found a more educative procedure than those forms of active and passive movements in which the patient's attention is concentrated upon the stump itself. And similarly the tethered football game with its necessarily rapid movements and balancing teaches the leg stump to function better than voluntary exercises opposed by some mechanical contrivance.

These last, however, have their place in the training of those muscles which owing to loss of opponents or adjuvants must acquire abilities not previously demanded of them. As an example of such a condition may be mentioned the common abduction and external rotation of the thigh stump, resulting largely from the loss of the normal action of the adductors. The remaining musculature has been found greatly improved by an active mechanotherapy which ensures its correct position at rest and in action.

Many investigations regarding features of a nature similar to the one mentioned have been made by the physiotherapeutists on the Staff of Hart House. Some of the conclusions reached have been already published. Others are receiving further confirmation and will be available later. The result of the work may, however, be broadly stated to be conclusive of the immense advantage, in many instances the necessity, of complete functional retraining in the majority of cases which have suffered a loss of function.

Artificial Limbs.—The manufacture of artificial appliances for the limbless was from the beginning undertaken as a State measure in Canada. In July, 1916, a factory was opened in Toronto. In spite of the most thorough search it was found impossible to discover a sufficient number of trained limb-makers to cope with the work. All the trained men on this continent other than enemy-aliens had been employed by England and France. The training of disabled men in the work was therefore undertaken as soon as they were available. This has resulted in a most satisfactory solution of the problem and has in addition provided suitable employment for a considerable number of disabled men in the central factory and the branch factories and fitting rooms of which seven have been established at various centers in Canada. The business of manufacturing and providing such appliances as have been proved most effective is being most satisfactorily accomplished. In view of the fact that the Government has assumed the responsibility of maintaining all artificial appliances in repair and renewing these when necessary it is clear that the demands for men trained in this work will not immediately cease.

Experiments have been made with the Italian idea of kinematic protheses for the upper extremity. It has been found on the whole that, however wonderful these appear in the performance of extraordinarily fine movements, they are not appreciated by the men, who prefer a simpler type of working stump. That type which has been found most effective on the whole is an arm which ends in a simple chuck, into which essential implements may be fixed. For dress purposes a hand with flexed fingers and an adjustable thumb is provided. The difficulties of providing a suitable artificial leg are much less than exist in the case of the arm. The knee joint lock, easily released when the patient sits down, and the ankle joint which permits of flexion by means of a spring attachment form an integral part of those approved and supplied by the Government factory.

Besides artificial limbs other orthopædic accessories are made and distributed. Probably the appliance second in importance to the prosthesis is the orthopedic boot. For many disablements of the lower limbs the specially built boot is of extreme value. Indeed for those who have lost one leg it is generally found necessary to provide as well as an artificial leg a specially strongly constructed shoe for the sound foot.

An ingenious arrangement also has been devised for cases of wrist drop in which the contraction of the unopposed flexors is prevented and an artificial extensor apparatus is provided by a spring mechanism attached to a cuff on the arm and a fingerless glove on the hand.

In addition to these, elastic stockings and supporting belts are made to the measure of the individual patient. Spectacles, arch supports, trusses and whatever other appliances are required are provided and maintained free of charge.

In this connection it should be noted that it has been found very advantageous to provide a temporary limb of the "peg" type to which in armless cases the various implements may be attached, and on which the leg-less may begin to get about. These are employed in every case just as soon as the condition of the stump will permit of it. They help greatly in the re-education of the part; and when combined with vigorous massage and active mechanotherapy they reduce very materially the period of shrinkage. Thus not only is the stump ready for its permanent limb much earlier than used to be the case under the old method of leaving nature to its own unaided efforts in effecting the shrinkage, but also when the permanent limb is put on, the stump is found to be already in a condition to make good use of it.

Vocational Training.—One result of the upheaval of 1914, has been the clarification and crystallization of many nebulous ideas and aspirations among which the communal mind was dimly groping its way forward. Of these one of the utmost importance was the question regarding the extent of the responsibility and duty borne by the community as a whole to each of its individual members. When the question first presented itself it was agreed without discussion that no other course could be followed than the assumption by the State of the duty of restoring to economic independence the citizen disabled in its service. So far had human society unconsciously advanced in the last two or three generations that the idea was scouted of allowing the repetition of the invariable aftermath of previous wars in the way of crippled men eking out a useless existence on a more or less insufficient pension. It was universally recognized that measures must be taken to prevent the recurrence of this unhappy spectacle.

A study of these measures was inaugurated in

every country. Among the allied nations Belgium and France, who had had some experience in the re-education of men crippled by industrial accident, began the application of this knowledge to wounded soldiers. They indicated the direction in which success should lie. It was clear from the first that the problem could be solved only by equipping them with such trained faculties as would enable them to meet their uninjured fellows on a basis of full equality. When the training of such men was first contemplated it became apparent that satisfactory answers could not be made to many of the questions raised. A new department of social activity was being opened in the venture and original investigations were necessary for the satisfactory solution of its particular problems.

When the work was begun in Canada the only available literature upon the subject of the restoration of the crippled soldier was to be found in a short report by Dr. Bourillon, published for the French authorities. Unfortunately the conclusions therein drawn were considered to be on the whole inapplicable to Canadian conditions. F. H. Sexton, Director of Technical Education in Nova Scotia, also submitted a report upon the possibilities of an activity of this nature. The major part of the Canadian organization has been carried through by Mr. E. H. Scammel, F. C. I. S.

The solution of the Canadian problem has been sought by investigation along two lines, of which the first consisted in the examination of groups of returned disabled men as to their physical capacity for returning to their previous occupations, as to their mental attitude to a return if such was considered possible, and as to their remaining undamaged abilities the training of which would fit them for independent economic existence.

This investigation revealed first of all the fact that the majority of the disabled should be able to return to their previous employment as soon as their convalescence had been completed, and that therefore the percentage of those whose disability would necessitate retraining was comparativly small. It also demonstrated another most important fact. It was observed that all instruction which occupied the attention of the convalescent, engaged his interest, and diverted his mind from his disablement, had a very marked effect upon his well being, hastened his physiological cure, and therefore deserved a very important place as a therapeutic measure. Thus the problem of economic restoration studied from this angle provided the medical profession with a new, or if not new at least a little realized or less acted upon, curative agent, the immense value of which is only now beginning to be fully appreciated.

The second line along which the problem was investigated in Canada consisted in a study of many individual trades and employments. In all about 900 occupations have been analyzed. The possibilities of those trades which offer suitable employment for disabled men has been elaborated. The field of employment of those suffering from all of the ordinary disablements has been mapped out.

As soon as the plan of retraining was instituted, a further difficulty presented itself for solution. It was observed that injured soldiers were most reluctant to embark upon vocational courses from the fear that proficiency would result in a reduction of their pensions. There can of course be nothing which will act upon a crippled man as a more powerful deterent to effort towards economic independence than the idea that a doubtful or temporary success will cause the forfeiture of an advantage which continued idleness will inevitably ensure. In this regard the Workmen's Compensation Laws have something to learn from the economic experience gained in the war. In many of these laws a return to gainful occupation is followed by the loss or reduction of compensation. The injured man prefers the good of which he is assured to the unknown and uncertain advantage that might be gained by effort. The natural tendency against exertion is thereby greatly enhanced. The legislators will undoubtedly learn this fact of elementary psychology and will amend the error common to nearly all Compensation Acts.

In round numbers Canada enlisted half a million men for the war. The population of Canada is about eight millions. Approximately therefore one out of every fifteen Canadian citizens joined the colors. Roughly speaking of those who enlisted 50,000 died of wounds or disease on service, and as many more have already been discharged with disabilities due to service. This is the material upon which the investigators of vocational training have had to work.

The percentage of those actually unable to return to their previous employment has been for several reasons as yet difficult to determine. First, the disabled and pensioned ex-soldier, fearing, in spite of all assurances to the contrary, that the fact that he is self-supporting will reduce his pension is apt to conceal his economic activity. Secondly, the state of the labour market has been such that numbers of disabled men have found employers all too anxious to engage them, however ill-equipped they might be for the positions offered. Thirdly, the possibilities and advantages of retraining are only now becoming widely known. Every day the opportunity for training is being seized by men many of whom, discharged some time ago, undertook employments in which they have finally found themselves unable to compete on even terms with their sound fellow workmen. It is now estimated that approximately 10 per cent. of the disabled will require a course in industrial training.

To qualify for a course the applicant must have a war-engendered disability which unfits him for his previous occupation. His application is made to the Vocation Training Board which sits constantly in each district. This board is composed of a doctor, a civilian, preferably a laborman or an employee, and the vocational officer. Each case is investigated with the utmost care and if approved the application is sent to the central authority for final authorization. The number of applications refused is approximately ten in every hundred received.

The principle upon which the choice of an occupation for the individual applicant is based depends almost entirely upon his previous employment or his obvious aptitude. Upon these it is necessary only to construct a good superstructure of special training, whereas if these were not carefully investigated and made use of it would, in the majority

of cases, be necessary to begin with the elements of the work. For example, the disabled stone mason is given a course in architectural draughtsmanship. His previous knowledge of building stands him in good stead. Were such a man to be taught automobile operating his earlier experience would be wasted.

The type of training given is of three kinds. First there is provided ward training, divided into bedside-therapy for those who are bedridden and ward-therapy for those who are allowed to be up but are confined to the wards. The occupations taught include embroidery, basketry, raffia-work, wood carving and weaving. Secondly, in every hospital accommodation is provided for occupational workshops and classrooms. The patients are instructed in the use of machines of several kinds and in typewriting, shorthand, mechanical drafting, motor mechanics, and other similar subjects. It is in this division of the work that the marked therapeutic benefit of employment is clearly observed. Also these classes stimulate many men to a continuance of their training on discharge from hospital. By these means too, the aptitudes of the individual men are demonstrated and the selection of the best form of occupation training for each is greatly simplified. Thirdly is the official course known as industrial training.

In round numbers there are at the moment of writing 2100 men taking training courses; 7700 have been approved for training and are awaiting complete convalescence to embark upon a set course and 2000 more are taking preliminary or temporary courses before their hospitalization has been completed. It is expected that somewhere in the neighborhood of 20,000 or 25,000 men will take advantage of the opportunities thus offered.

So far 2,569 men have completed definite courses of training in 177 different trades. These comprise such varied occupation as armature-winding, agriculture and wheel-truing, embalming, flower growing and trombone-playing, poultry raising, automobile operating and gas-fitting. The courses are given in the technical departments of several of the Canadian universities, in schools of technology, in schools specially constructed for the purpose, and to a growing extent in the workshops of many manufacturing concerns. In every case the utmost care is taken to ensure the fact that the disabled man will be so thoroughly trained as to be able in spite of his disability to compete on equal terms with his uninjured companions. During his course of training every man is paid a wage equal to his army pay.

An interesting analysis has been made of the figures respecting men whose training has been recently completed. Of these 65 per cent. are engaged in the occupation they have learnt and 18 per cent. are employed in other trades. Of the remainder 9 per cent were not traced, 2 per cent. were ill and 6 per cent. were unemployed. It is thought that most of these last were enjoying a holiday on the bonus, amounting to a month's pay, which is given to each man who successfully completes his course.

Incidentally it may be remarked that the training courses have had a two-fold benefit. Primarily, they have taught the disabled man a particular trade. Secondarily, however, they have taught him something of which he was inclined to be very doubtful, namely that he could actually do useful work after all. In conclusion it may be stated that the majority who have faithfully applied themselves to a course of training have acquired such an addition to their equipment that in spite of their disabilities they are better fitted for the struggle for economic existence than they were before the war.

Employment.—The necessity for provisions for the replacing of demobilized soldiers in productive work was realized very early in the war. In the autumn of 1915 a conference of provincial authorities was held to discuss and report upon a consistent scheme for the country as a whole. Such a conference was necessary because the governmental employment bureaus then existing were under provincial control.

When war broke out there was a certain amount of unemployment in Canada. A year later many employers were forced to engage women, male labor having already become very scarce. The shortage of labor confined the earlier activities of the provincial employment commissions largely to a general oversight of the welfare of returned men. Only of late has the need become urgent of intensive employment-bureau work.

The system which has been followed has involved the canvassing of employers and ascertaining the opportunities each would provide for the employment of disabled men. Labor bureaus have been opened in all the principal towns and cities and the returned soldiers are afforded the first chance for vacant positions. A follow-up scheme is also in operation by which satisfactory relations between the employer and the disabled employee are in the vast majority of instances being maintained.

Pensions.—In June, 1916, there was established the Board of Pensions Commissioners for Canada, to which was delegated full authority for the administration of newly formulated pensions regulations. These regulations provided at that time the most generous indemnities existing in any of the allied countries for disabled men, and for the dependents of those who had been killed or had died on service. There were included also three principles of vital and fundamental importance. The first of these prohibited the consideration of prewar occupation in the estimate of the pensionability of a man who had suffered a physical detriment on service. The second forbade the reduction of pension because of subsequent economic success. In a third it was provided that all disabilities, whatever their origin, occurring or aggravated on service should be pensionable, save those resulting from vicious or improper conduct.

This legislation was the most equitable, the most inclusive and from the point of view of the applicant the simplest in operation of any known system. Those responsible for it had appreciated the fact that the same standard by which men had been judged as to their physical fitness for service must be that against which their deficiency for civil activity should also be measured; that the only common ground upon which they had all stood at enlistment was the possession of normal healthy bodies and minds; and that the lowest common denominator in the matter of employability was the un-

trained labor market. These form the fundamental features of Canadian Pension Legislation. So far their application has proved that they are economically correct.

At the time when this legislation was first passed the amount payable for total disability was $480 per year. This was the sum held to be that necessary to keep in decent comfort a man unable to contribute to his own support. It has since been increased to $600 a year. When the smaller amount was authorized it was the largest sum paid from a public treasury as a pension for a war-engendered disability. The increased amount occupied the same relative position. France has recently approved of a measure to increase its pension rates on the basis of the cost of living. In that country there is now paid $480 per year as a total disability pension. This is the same sum as is paid in New Zealand. It is not impossible that the total disability amount may, for the same reasons as were advanced in France, be increased in Canada to be more in keeping with the actual cost of living. It must not be forgotten, however, that in addition to his own pension a married man received an extra allowance for his wife and for each of his children, and that these allowances are also payable in the case of unmarried men to such relations as parents, younger brothers and sisters and so on who are actually dependent upon him.

The estimated pension bill for this year is thirty million of dollars. It is anticipated that at its maximum it should not exceed fifty million dollars. It is hoped that the generosity of the provisions of this legislation, the equity of the principles upon which it is based, and the solid body of enlightened opinion supporting it, will prevent a repetition of the experience of the United States in regard to pensions after the Civil War.

Other Economic Measures.—In addition to the economic measures above outlined, several Governmental activities should be mentioned. These include the payment of a war-service gratuity calculated on the basis of length of service. The maximum sum so paid is equivalent to six months army pay. The intention of this measure is to provide each soldier with money enough to enable him to readjust himself in civilian life without imposing upon him the necessity of seizing the first job that offers itself in order to avoid hardship. It is believed that dislocation of the labor market is not so likely to occur because of the interval of freedom from urgent need secured by this measure.

The other measure of which the preliminaries have now been satisfactorily settled is a scheme of land settlement. It is planned to establish farming districts, each of which will include a communal center. The land is to be acquired on an easy payment scheme, the period of payment is to cover twenty or thirty years, and the soldier-settler may obtain an advance of $2,500 for the purpose of procuring materials for home-building and the essential implements. It is hoped that by a careful selection the applicants for land under this scheme, by thorough courses in agriculture, by continued instructions, and by careful supervision, that the result of previous attempts along similar lines to effect a genuine settlement on the land by discharged soldiers will be avoided.

The Future.—In the older countries there has been of late years an increasing tendency towards the assumption by the State of the duty of providing for those of their citizens, for whom such activities are most necessary, both medical attention and social insurance. These communal efforts have seen their greatest development in England and Germany, where for some years there has been provided sickness, accident, old age, and unemployment compensation. In the younger nations the social mind was not until the war educated to the realization of the advantage of these measures.

Canada is, comparatively speaking, a small and extensive country to have embarked upon a scheme for the continued State care of a considerable proportion of its citizens as comprehensive as that outlined above. A realization of the necessity for it was, however, brought home to the Canadians early in the war. The organization has become highly developed. Its facilities are already great and are being continually increased. The quality of the service it affords is constantly improving as knowledge grows. Its application to the people as a whole would seem to be almost inevitable. Indeed to allow of the dissipation of the organization upon the completion of its immediate task would be as regrettable a failure "to seize the skirts of happy chance," as one could well imagine.

With some modification the same measures of medical care and economic adjustment might well be made available under governmental direction to every citizen. The continuity and consistency of the arrangements would thus be secured for all time. The resulting advantages could to-day hardly be imagined. The possibilities offered in various occupations to those suffering from specific disabilities would rapidly come to be recognized as based upon a sound scientific foundation. The incidence and extent of many diseases and disablements would be determinable in a way not now possible. Their control could be effected to a degree not now realized. Such an extension of a scheme, which had its origin purely as a war-measure, could not but result in immense and incalculable benefits to society at large.

Scientific Gains.—There has not as yet been time for a minute and thorough analysis of the medical records of the war. Those advances in knowledge which seem, however, to have been the most outstanding are to be found in four subdivisions of medical science; and whatever future study may reveal certain facts are at the moment worthy of remark.

In internal medicine confirmation has been given in innumerable instances of the immense advantages to be gained by preventive measures. It is platitudinous to remark upon the extraordinary ratio, never before witnessed, between the mortality and morbidity from wounds and from diseases throughout the war. When one thinks of the vast numbers of men who have lived for five years in the closest communion confined to and without a change of the small area in which the war was fought, and of the immense difficulties of providing and maintaining the essentials of sanitation, it may easily be realized that the great lack in modern society, as a result of which many diseases tend to increase rather than to be diminished, is the

absence of that discipline by means of which the almost complete elimination of many infections was effected. Where discipline was good preventive inoculation was consistently given, food was properly cared for, water was satisfactorily purified, and men and quarters were kept thoroughly clean. Under such conditions infectious disease was reduced to a minimum. Where discipline was not so good, its relaxation was almost invariably marked by an increase in the number of those whose services were temporarily or permanently lost to the army from illness. Is it not possible to awaken public opinion to the advantages to be gained by these measures, and the necessity of a strict enforcement of the laws regarding sanitation?

The extent to which nervous disorders functional and organic obtain among peoples who assume that their national health is sound has been immensely greater than could have been anticipated. Approximately 10 per cent. of men returned unfit for service suffered from psychoneuropathies, among which hysteria or war-neurosis had a very marked preponderance. Figures have been published showing that when the examination of recruits is carried out by the most modern methods approximately 1½ per cent. of those examined must be rejected on account of pathological conditions of the nervous system, and that in spite of this rigorous selection the stress of service under present-day conditions of warfare reveals very many undetected cases. It is difficult to know what deductions should be made from these facts. Their publication has undoubtedly stimulated a discussion of the situation, and the future will decide the question of their importance.

It is outside the scope of such a paper as this to attempt even to outline the advances made in surgery. Reference may be made, however, to the new conceptions that have been arrived at in certain matters of technique and of the vulnerability of tissue. There has been a very material change in the methods employed in the surgery of the chest and of joints, and a tremendous amount of work has been done in connection with the repair of severed nerves and in the transplantation of tendons. The lessons thus learned will apply to civilian surgery more by reason of the fundamental facts they have established than by their immediate application in practice, because it is to be hoped that war-surgery may be forever a thing of the past unenlightened ages, and that the thousands of wounds of brains, nerves, muscles, and bones, resulting from enemy activity will be counted in tens where only the dangers of civil life must be faced.

In therapeutics the greatest advance has been made in function training. Physiotherapy, in which are included massage, electro and hydrotherapy, mechanotherapy and therapeutic games and trades, has made great strides in every country and instead of being relegated to the position of a useful but unessential adjuvant, has come now to be recognized as one of the most important elements in the surgeon's armamentarium. Perhaps from the broadest standpoint it may be said that in this department the greatest gain of all has been made and that in the future the medical profession will be held as responsible for the restoration of function as it is to-day for physiological repair.

Conclusions.—In several respects the last few years have witnessed a progress of scientific knowledge which in the less stimulating atmosphere of peaceful pursuits might have covered a period ten times as long. Several of the greatest and most civilized nations have now been recording figures of immense importance regarding the health of large numbers of selected citizens. These records have yet to be collected, to be studied, and to be analysed. From them it is not too much to expect that many facts of the utmost importance will be revealed.

The advance in therapy has been marked. The world over, measures have been elaborated for the care and restoration of the disabled soldier. There are immense possibilities in the extension of this scheme to the nation as a whole. The advantages that would undoubtedly ensue are incalculable.

In conclusion may one not say that, in spite of its horrors and its unavoidable sufferings and sorrows, in the last analysis the Great War will be found to have conferred upon the present generation of medical men an unrivalled opportunity?

FUNCTIONAL RE-EDUCATION OF THE BRITISH SOLDIER.*

By R. TAIT McKENZIE, M.D.,

MAJOR, MEDICAL CORPS, U. S. ARMY.

Mr. Chairman and Members of the New York Academy of Medicine:—I must crave your indulgence if I do not give you a very scientific paper, because the remarks I am about to make are based partly on personal experience and are partly historical. I will leave to Dr. Gilman Thompson the task of bringing the description of this work of rehabilitation of the disabled up to date.

In the early part of the war, shortly after the great armies were gathered together, and the task of giving them physical training in the training camps was undertaken on a large scale, it was found that a great many men were unfit to take this training through physical defects which were remediable. In one camp, at Portsmouth, an inspection of the unfit showed some men with slight defects which escaped the scrutiny of the medical officer, but in addition some were found who were entirely unfit for military duty, usually married men, for the British Government had made very liberal provisions for the families of enlisted men, with the result that many unfits were glad of the opportunity to enlist and succeeded in getting in, in spite of the examiner.

A little later, when the wounded began to come back, the large general hospitals became so overcrowded that the men could not be properly cared for. The overcrowding reached such an extent that the commanding officer of a hospital was not so much occupied with curing his patients as with getting the beds empty to accommodate the ever-increasing tide of wounded coming from the front. Under these conditions it becomes necessary to resort to all sorts of makeshift hospitals. Country homes with local doctors were pressed into service, with the lady of the house a chief cook

*Read, with lantern slide illustrations, at a meeting of the New York Academy of Medicine, March 6, 1919.

and her friends as improvised nurses, taking care of the patients as best they might. Conditions thus became deplorable, and the men sometimes got out of hand and would not submit to discipline or to the long course of treatment essential to their restoration. Many disabilities which originally were remediable became permanent, and it finally became evident that it was essential to get these men back under discipline in order to carry out the necessary treatment in camps for this purpose.

Sir Alfred Keogh, D.G.M.S., finally decided to organize camps for convalescents under a system whereby each camp would care for about four thousand men and would be commanded by an officer from the front who would keep the men under military discipline, but instead of the strict military training of a mobilization camp, suitable remedial exercises were given, and then treatment consisting of physiotherapy in all its forms. Where it was possible, the men were entirely restored and returned to the front, and where it was found that they would never be fit for full active service, they were placed in sedentary work on the lines of communication in various parts of the British Isles, or in civil life.

In all, there were sixteen such camps, each later having a capacity of five thousand men, though they were not at all times up to full strength.

At the period of the war, when the voluntary system of enlistment had reached its limit, five million men had volunteered, and the quality began to run low. The regulations for entering the service had to be reduced to meet the actual conditions. As a result of this lowering of standard for height and weight, they had the so-called "bantam" regiments, and it was not until conscription came in that the quality of the man power again rose.

Among the reconstruction centers was the one at Heaton Park, near Manchester, where the men were lodged in huts, arranged about a central administration building. The administration building was originally an art gallery, and the camp was originally designed for Manchester regiments. It was refitted to provide physiotherapy, electricity, and massage, hydrotherapy, and progressive physical exercises.

The disabled men were divided into four groups as follows:

Class A—Those who were fit for active service.

Class B—Those who were fit for service on the lines of communication.

Class C—Those fit for home work only, and

Class D—Those who were still under treatment and still unclassified.

Some of these men were over military age and all were badly wounded or incapacitated, so that they furnished a very difficult administrative problem.

There were attached to the camp, a corps of forty masseuses. We had also masseurs—men who had been blinded in active service and were later trained at St. Dunstans under Sir Arthur Pearson. The work these people did was above praise and it is due largely to their efficient services that the excellent results attained were made possible. It was necessary to improvise facilities for the application of hydrotherapy, and for this purpose we took an ordinary "mess hut" and built an engine house for heating the water. The hut was divided into rooms, fitted up with douches and baths. The neutral bath, at a temperature of about 93° was more used than any other. This was a large tub or tank provided with a seat to accommodate twelve men at one time. The water was kept constantly at a temperature of 93°. It was used chiefly for cases of shell shock with rapid pulse and heart action. It was found to be of the greatest benefit for such cases. After the men had been in the bath for twenty or thirty minutes they were taken out, wrapped in blankets, and rested in bed. A bath of this kind was given every other day, and on the alternate days the men were taken for a slow walk, using a walking stick and resting when they felt like it. This was found to be an excellent treatment for "nervous" cases, those suffering with tremors, hallucinations, and the various neuroses familiar to those engaged in war work. For local conditions of the limbs, the best results were obtained from the arm and leg baths, called by the French "au courant" and by the English "whirlpool baths," because the water was supplied from a number of nozzles, and so kept in constant motion and at a temperature of 112° up to 118°. The patient sat on a stool with the arm or leg, as the case might be, in the bath. For great areas of scar tissue, where the limb was blue, cold and sweaty, keeping it in this bath for twenty minutes was extremely beneficial. The limb would come out crimson in color, painless, and prepared for the manipulations of the masseur. Many men with painful stumps, due to extensive cicatrization, were greatly relieved and were enabled to get sufficient respite from their sufferings to sleep.

Combined with hydrotherapy, electricity was used in various forms, but the electro-therapy was not carried out in all its refinements, owing to the impossibility of installing all the apparatus that was required. Ionization, however, was used for scar tissue, this being obtained by a saline solution and iodide of potassium in the arm or leg bath.

Along with these methods, dry and radiant heat was employed as a preliminary to massage. This treatment with radiant heat was found to be most beneficial in the scars resulting from tearing wounds of the back, of which there were a great many, owing to the fact that the men lay down on their faces to escape shell fire, and were struck in the back by falling shrapnel.

The general method followed was first to prepare the joint or part either by wet or dry heat, preliminary to massage. As mentioned before, many of the masseurs were men blinded in the war. One of these men was blinded as the result of a bullet's going in at the left and out at the right side of the head, severing both optic nerves. He became a very skillful masseur and is now doing private work and making from $15 to $20 a week.

In the application of treatment, it was not only necessary to employ massage and passive movements, but it was essential that the patient should be stimulated to make the effort to use the joint

himself. In looking about for apparatus, we found that the Zander apparatus was the only one on the market, and these were very high priced and scarce, the supply available being entirely insufficient to meet the requirements of the reconstruction hospitals. To meet the emergency, apparatus was devised. An old sewing machine was pressed into service. This furnished an exercise by which a tendon Achilles was stretched, and motion on a stiff ankle increased. Another apparatus was devised for finger exercises that furnished exercise in both flexion and extension. This apparatus could be attached to a table and the men could be seated while they went through their exercises.

As the men gradually improved, they were put to work on pulley weights in classes of eight or ten. Every day, after a man has had his massage, he is put to work at some voluntary form of exercise, which is gradually increased in vigor. Later, these men are grouped in squads of twenty to fifty for drill. The men were all lined up in squads and those who were able to do all the movements did so, while any man whose disability prevented him from taking a certain exercise stood fast while the others did that movement. Such a man was noted by the inspector, who examined and questioned him and saw that he received any special treatment that his disability required. We found that this was a much better plan than putting men with special types of injuries in classes by themselves. In addition to simple movements, there were balance movements, which were found to be of special value in cases of neurosis, ataxia, etc. A beam was raised 18 inches or 2 feet from the ground. A man suffering from neurosis, when he first undertook to walk along it would often tremble, perspire, and generally go to pieces.

A large number of cases had been gassed, but had no organic heart or lung trouble; they were merely neurotic. These men were given rhythmic breathing exercises, but no attempt was made to have the entire class adopt a certain rhythm; each man used his own rhythm. The tendency of these exercises was to slow the rate of respiration.

Another test given the men before they were returned to active service was going through wire entanglements. This necessitated knee raising, balancing, and the estimation of distance. Small groups of men were taken for progressive walking exercises. They were under the charge of a sergeant and first took the light walk of 2 miles, and then a 4-mile route march in regular army formation.

Specific instances of different kinds of disabilities in men put back into active service were shown in the pictures.

After a man passed various tests he was assigned to Class A, if fit for active service, and these men were divided into squads, according to the regiment from which they came. As soon as the squad numbered fifty or sixty men it was conducted to a receiving depot and the men drafted back into the service. We were able to put about 40 per cent. of the men into Class A.

We found that ankyloses and Volkmann's contracture were often difficult to handle when the part had been kept in splints too long, but, nevertheless, some most remarkable results were obtained in these cases.

In many stumps, the nerve terminations had been caught in scar tissue, with the result that the men suffered a great deal of pain. Radiant heat frequently afforded the greatest relief. One patient finally made a recovery after 113 wounds, and I am showing him to you because he illustrates an interesting feature about massage that we did not recognize before the war, namely, that massage frequently starts up active inflammation about a foreign body or sequestrum and assists in speeding its removal.

An interesting case of malingering came under our notice at Heaton Park, which serves to illustrate the ingenuity of some of these men in avoiding active service. This man reported for massage every day with a swollen hand and arm, and received treatment, though no one was able to explain the reason for the condition. After he was treated for two weeks it was discovered that he tied a cord around his arm and then hung it over the side of the bed during the night, with the result that he presented this swelling every morning.

Early in the war there were many cases of distressing facial deformities which offered a very difficult problem for solution. The effect of these facial deformities was most depressing on the men. They also had great difficulty in obtaining employment because they were so repulsive and very often they felt that their presence was not welcome, even in their own families. Later on, after the introduction of the steel helmet, the number of these facial injuries became much fewer. The sad plight of these men has now been greatly alleviated by the facial masks, which were first devised by Captain Derwent Wood, A.R.A. These masks were made of a thin film of copper, painted in the natural colors of the human face and attached by means of glasses. I have had some experience in the making of these masks and we find that we can make a face look as good as the man's old one, and sometimes better. These masks have a great field of usefulness in civil life in cases of facial deformity, due to rodent ulcer, carcinoma, or to any other cause.

2014 Pine Street, Philadelphia.

FUNCTIONAL RE-EDUCATION OF THE FRENCH AND AMERICAN SOLDIER.*

By W. GILMAN THOMPSON, M.D.,
NEW YORK.

Dr. Thompson said that after the Civil War the country was filled with old soldiers who joined the G. A. R. and paraded on Decoration Day and Fourth of July and spent the rest of their time in idleness and dependency. The public took the attitude that in serving his country the old soldier had done his bit and that it was right that he should be supported in idleness and in this attitude the men themselves acquiesced. About all any of these men ever did in the way of steady employment was to act as night watchmen or street

*Abstract report of an informal talk, illustrated by lantern slides, at a meeting of the New York Academy of Medicine, March 6, 1919.

vendors. Today, Dr. Thompson said, we had adopted an entirely different attitude toward the war cripple. We were not going to have a repetition of these conditions after this world war, for the reason that most remarkable results had already been achieved in England, France, Italy, and Canada in the rehabilitation of the wounded, and these results were now being duplicated in this country. These crippled men were being stimulated to make an effort to become independent, self-supporting, and self-respecting members of the community.

At the beginning of the war France had only one institution entirely devoted to the rehabilitation of the maimed and crippled, now they had 124 such institutions, and similar ones had been established in England, Italy, and Belgium, with the very remarkable result that a very large percentage of the mutilés had been restored to lives of usefulness and self-support. From Britain some 40 per cent. were sent back to the front, and in France 80 per cent. had been shown to be capable of return to gainful occupations. In some instances these rehabilitated men were earning more than they originally did, this being due to the experience gained in the method of handling disabled men, which was somewhat as follows: The injured man came first for a physical examination, which was made with great thoroughness—with all sorts of accurate measurements as to his lost power and his remaining strength. After the physical examination was completed he was turned over to a "pedagogic adviser," who found what the man had been accustomed to do before the war, rated his ability, and recommended him for certain kinds of trade or occupation. Then another officer took the crippled man in charge and conducted him through the various departments of the work-shops where he might see other maimed men and could observe the great facility with which they were able to accomplish many kinds of work and could see the system of training.

The speaker said that he was associated with two important institutions engaged in this work, namely, the Clinic for Functional Reeducation, at 5 Livingston Place, and also the School for Gardeners at the New York Botanical Gardens. When a man was properly fitted with an artificial limb a great many occupations were open to him. One type of artificial arm contained a socket into which various tools could be fitted, and the man could acquire such skill that he could do almost all kinds of carpentry work. With an artificial arm he also could handle garden tools. In fact, there was scarcely any limitation to the trades open to the maimed. A most important feature of the work in connection with the rehabilitation of these crippled men was that of educating the public and employers of labor to recognize that they were as valuable to the employer as normal men, sometimes more valuable because of their intensive training and the fact that having once secured employment they were less likely to make changes.

As to the degree of skill that might be obtained in coordination with an artificial limb the audience might judge from the pictures showing a man playing a violin and another sharpening a scythe. It was also of interest that there was in this city a man who was an expert billiard player though both forearms had been amputated.

Dr. Thompson, in speaking of the work at the Clinic for Functional Reeducation, stated that a large sum of money had been put at his disposal for this work, and as the New York Infirmary for Women and Children had temporarily suspended work through lack of funds, the Clinic had rented a portion of its building and had installed various forms of apparatus for the application of electrotherapy, hydrotherapy, mechanotherapy, etc. This Clinic was in operation as soon as the crippled soldiers began to return, and was occupied also with the reconstruction of industrial cripples. During the past six months they had treated some 500 patients, not all soldiers, but a large percentage from the Marine Service, the War Risk Insurance Bureau, and the Federal Board for Vocational Training. Illustrations of the apparatus used at this Clinic for restoring lost function were shown which were of particular interest as they carried a dial on which could be registered the patient's exact strength so that he could see for himself each day just what progress he was making. This had been found of great value from the psychological standpoint as the patient could see his improvement and was thus greatly encouraged and stimulated to further effort by volunteer workers. The whole object of the treatment was to have the patient do the work himself for when he did this he forgot his aches and pains and this was a great aid in speeding his restoration. This apparatus was the invention of Major R. Tait McKenzie and Professor E. A. Bott.

The speaker showed pictures of a middle-aged man whom he found begging one day on the street. The man had lost his arm in a quarry explosion five years previously. He told the man about the Clinic and what could be done for him, and when he learned that it would cost him nothing he gladly consented to take advantage of the opportunity of fitting himself for employment. He finally was trained so that he could use artificial arms, but he was an Italian and could not speak much English. They had made every effort to get employment for him but had been so far unsuccessful. This illustrated the problem with which they had to contend, the education of the employer of industrial labor. There were in the hospitals of New York each year two hundred major amputations performed, the patients being discharged as "cured." They should not be accounted "cured" until they had learned to use an artificial limb and had become self-supporting.

One phase of the work in which Dr. Thompson said he was especially interested was that being done in training disabled men as expert gardeners at the New York Botanical Garden in Bronx Park. In France there were a large number of wounded soldiers trained in gardening, and the French seemed to take to it much more readily than our men did. However, there was a field for this kind of work in this country since heretofore we had gotten our foremen for large estates and our expert gardeners mainly from Scotland and Germany. It was one object of this school to train men especially for this work.

In closing, Dr. Thompson expressed the opinion that functional reeducation had come to stay in this country. There was a great deal to be done for the after-care of industrial cripples and what we had learned in the war emergency would be applied continuously in times of peace to the industrial cripple.

THE PANDEMIC OF INFLUENZA.

INFLUENZA has never been so widespread and created such havoc as it has during the recent pandemic of the disease. In India alone it is said to have caused the deaths of 5,000,000 persons, as many as the plague has destroyed in that country of pests during the past twenty years. According to *Public Health Reports*, April 18, 1919, over 40 per cent. of the inhabitants of South Africa were infected with influenza in the four months during which the epidemic raged. For the 6,115,212 population this means 2,616,805 cases of influenza, and of these 139,471 were fatal, a case mortality of over 5 per cent. The case mortality among those of European race was less than half of that among non-Europeans, the respective rates being 2.57 and 5.90 per cent. In South Africa it was found that persons in the third and fourth decades of life were particularly susceptible to attack by the disease, and the death rate was also greater in these age groups. A large number of instances were also noted where the disease resulted in miscarriages. Moreover, there was a high mortality among pregnant women.

In the Pacific islands the disease spread like wildfire and was particularly deadly. A correspondent of the *New York Times* from Fiji states that in what was German Samoa there are now more than a thousand children who were orphaned by influenza, and Colonel Robert Logan, the New Zealand Administrator of German Samoa, reports that there were 8,000 deaths from the disease, two-thirds of these being men. The Apia correspondent of the Sydney *Daily Telegraph* is authority for the statement that at one time in that place 80 or 90 per cent. of the people were lying helpless. Many died from starvation who might probably have recovered, for even when rice, milk, and other food products were sent out and delivered, the survivors were too weak to prepare and apportion the food. On one day the burials in Apia numbered 71, and probably out of this small town and environs nearly 700 were buried. Most of the great chiefs of Samoa are dead, as well as the majority of the mission teachers and 56 per cent. of the government officials. A good many women also fell victims to the devastating scourge and some children, although the latter were largely immune.

Early in the year influenza, despite the rigorous quarantine regulations, appeared in Australia, although it was only in Melbourne that the disease gained a foothold. Up to the first of March the number of cases totaled about 8,000 and the number of deaths about 500. In New Zealand, where during a few weeks late in 1918 influenza caused almost 6,000 deaths, a pneumonic influenza epidemic commission began taking evidence late in February. The Australian military authorities at Rabane, the capital of former German New Guinea, fearing that if the disease became established on the mainland it would exterminate the natives, inoculated against influenza 6,000 to 7,000 aborigines in Rabane and vicinity.

According to a recent report from Port Arthur, Ontario, the grippe has caused the death of at least 200 out of the Indian population of 1,600 in that district. During the epidemic entire families were taken ill and, unable to get help from any source, starved to death.

It is plainly evident that no former outbreak of influenza was so world wide as the most recent one and probably none so destructive to life. This, however, can be easily understood, first because means of communication are so easy, and second, because when any infectious disease falls on virgin soil and when sanitary and all preventive measures are lacking, it always spreads rapidly and is of a very deadly nature.

LATENT MICROBISM.

IN 1886 Verneuil proposed the theory of latent microbism at the Academy of Medicine of Paris in the following words: "I call latent microbic parasitism a pathological state characterized by the existence of pathogenic germs in various parts of the organism, external or internal surfaces, cavities with or without communication with the outside, vascular system, connective tissue interstices, etc., remaining inactive during months or years and giving rise to no symptom until the day when some cause arises which lowers or even destroys the health." In other words, it may be said that latent microbism is an infection limited to a small area and giving rise to no apparent sign, a microbic colony in a state of inactivity, but which may awaken and become active when some disturbing cause, traumatic or otherwise, arises and manifests its presence by phenomena of local, general, or metastatic infection. Therefore, two factors must be in play in latent microbism; firstly, the presence of a bacterial agent in the organism before the advent of the disease, and secondly, conditions favoring the awakening into activity of these pathogenic agents.

An apparently perfectly healthy person may be a carrier of various microbes, and on account of its relations with the outside, the human organism is permanently invaded by infectious agents which, when once introduced, will act differently according

to circumstances. There are some whose presence immediately results in serious disturbances, gravely compromising the health and not infrequently leading to the death of the individual. Such, for example, are the microorganisms of anthrax, rabies, syphilis, etc. The others, although capable of yet worse destruction, nevertheless remain in the state of inoffensive parasites because they do not find conditions favorable for their evolution. They lead a latent life, their multiplication is slight, while they elaborate toxic matters, the quantity and quality of which are incapable of provoking morbid manifestations, and although nothing betrays their presence they should never be disregarded nor looked upon as negligible quantities. When they acquire sufficient virulence or when the organism loses those qualities which guarantee security from disease, contagion is not necessary; the disease breaks out spontaneously, as was said in the days when our modern notions of disease were as yet undeveloped.

It has now been demonstrated that several infectious agents are normally met with in the cavities of the body, as well as on the mucous and cutaneous surfaces. Along the digestive tract, the various species of microbic flora have their representatives awaiting the propitious time for infecting the organism. Military surgeons have recorded observations which appear absolutely demonstrative. For example, soldiers have been quartered in a village where typhoid fever was unknown, and suddenly, following fatigue, a case has developed in a soldier, then a second, and so on, until a small epidemic occurred.

Reumlinger and Schneider maintain that the typhoid bacillus is to be found in the intestinal contents of normal persons, while Rodet and Roux are of the opinion that the typhoid bacillus is only a variety of the *Bacterium coli*. If the resistance of the organism diminishes, the diseases arises spontaneously in appearance, but in reality it is the result of an exalted virulence of the intestinal parasite. Other well defined infections may likewise appear spontaneously. Such is the case in diphtheria when no chance of contagion can be discovered. This also applies to the staphylococcus, a common host of the cutaneous surface, in cases of the spontaneous development of abscess, furuncle, and carbuncle. The streptococcus lying latent in the buccal cavity gives rise to divers forms of angina and erysipelas. The pneumococcus living in the mouth invades the lung and pneumonia is the outcome, and then this virulently exalted germ may infect others; the disease born of autoinfection may then extend by heteroinfection or contagion.

But besides these aerobic bacteria, there is a series of others, quite as interesting and dangerous, which infest the excretory ducts of glands. Lippmann and Gilbert took cultures of the bile at different parts of the biliary tract and came to the conclusion that in the normal state almost the entire extrahepatic portion of the ducts is the seat of an abundant anaerobic microbic flora. The normal biliary microbism extends from the intestine up to the division of the hepatic ducts, involving the choledochus, gall bladder, and hepatic ducts, but the intrahepatic ramifications are sterile. The same applies to the pancreas.

Given this multitude of facts it is readily conceived what immense danger constantly threatens the human body. This latent microbism offers an always present morbid imminence, although it does not necessarily create disease. The harboring of morbid germs may last for an unlimited time, and it is this that constitutes the peril.

THE PREVENTION OF VENEREAL DISEASES.

WHILE, of course, it is agreed that every effort should be made to combat the spread of venereal diseases, the views as to the means to be taken to accomplish this object are various. On the authority of many practical medical men, among them Sir James Barrett, Surgeon in Chief of the Australian forces (*British Medical Journal*, Feb. 1, 1919), prophylactic treatment is of most avail. Barrett virtually stopped the spread of venereal diseases among the Australian troops in Egypt, a hotbed of such diseases, by enforcing venereal prophylaxis. With regard to the most efficient drugs for prophylaxis, according to Dr. C. F. Marshall (*Medical Press*, April 16, 1919), it is probable that a solution of permanganate of potassium, 1 in 1,000, is the best known weapon we possess against the gonococcus. Against the pallid spirochete, calomel ointment, 33 per cent., as originally recommended by Metchnikoff, is most generally used, but calomel is insoluble, and Marshall believes that an ointment containing a soluble salt of mercury, such as the perchloride, is to be preferred.

In Great Britain the educational campaign which has been carried on by the National Council for Combating Venereal Disease has been more or less of a failure, and recently this body compromised, to a great extent, by recommending "early preventive treatment," which signifies resort to "ablution rooms" situated in camps and public places where men may obtain irrigation and inunction with calomel ointment, under the direction of a trained orderly, in case of exposure to possible venereal infection. Marshall, however, believes in prophylaxis by the use of outfits, the method which Barrett found of most effect in Egypt. In Great Britain moral reasons are adduced against the legalizing of this practice, but the main argument brought forward is that they lead to greater promiscuous intercourse, and not being infallible would in the long run increase rather than decrease venereal infection. But, as Marshall says, this argument is based on the supposition that fear of infection is one of the chief deterrents against sexual irregularity, a supposition which is probably greatly exaggerated. Other reasons, moral and otherwise, are advanced. Taking into consideration, however, the existing situation as regards venereal diseases, and the disastrous results on the race, the matter should be

regarded rather from sanitary and practical standpoints than from a sentimental point of view. Marshall states unreservedly that the most effective method of dealing with the venereal diseases is by direct prophylaxis.

Absence of Cancer in the Arctic Regions.

It is reported by Dr. H. C. Ross in the *Lancet* of March 29, 1919, on the authority of Vilhjalmur Stefansson, the Arctic explorer, who has returned recently from an expedition to the Far North that cancer does not exist among the Esquimaux. Moreover, Ross has been told also by Sir William MacGregor, Dr. W. T. Grenfell, Mr. Frank Benzley, and Rear Admiral Peary that they had never seen a case of cancer among the native tribes of the Far North. If it may be assumed that cancer is absent from the Arctic regions, and the assumption seems justifiable, the fact, Ross says, gives rise to some interesting reflections. In the first instance, the Esquimaux are perhaps the most carnivorous race of human beings in the world, and consume few vegetables; therefore, the non-existence of cancer among them would appear to weaken one of the dietetic theories of the cause of this disease. There seems to be no racial or physiological difference which would exempt the Esquimaux from cancer, and, in addition, the observations of Panum, fifty years or so ago, that cancer was either extremely rare or did not exist in Iceland or Greenland, in the settlements peopled by Europeans, would imply that race does not enter into the question. Consequently, as Ross points out, the climatic explanation is the most plausible, and this tends to revive the parasitic theory of origin. The cold in the Arctic regions is too intense for saprophytic organisms to live, and diseases conveyed by aerial convection, such as "colds," are unknown. Ross is of the opinion that cancer may come in a similar category, and that its cause is an organism which invades the body from without which is air-borne in part of its life history, and which therefore cannot exist in the Arctic climate. If it should prove to be a definite fact that the Far North is free from cancer, then the search for a satisfactory explanation of this fact will be interesting.

Demineralization from Gassing.

Phenomena due to gassing will soon lose their interest for the medical man save when they parallel some feature of civil practice. In *Le Progrès Médical* for March 15, Loeper and Verpy call attention to a subject of much interest, to wit, demineralization, in connection with gassing, although apparently the lesions concerned are gas burns rather than internal injuries. The gas accused is the so-called yperite and the blood analyses submitted show that the total mineral matter as well as phosphorus in particular is notably diminished. The authors dwell on the great extent of the burns in these cases as if the demineralization were dependent on this factor. Control cases with other kinds of burns are not mentioned, and, as far as we know, the question of demineralization in ordinary burns has never been made the subject of routine investigation, despite the abundant opportunities offered. These yperite burns seem to be followed by a waste of phosphates in the urine which may amount to 5 gm. in 24 hours, and there is a further demand by the organism of mineral matter necessary to repair the damage done to the skin by the burn. When large blisters are formed as the result of burns an intoxication of a peculiar kind is set in motion, but this appears to have no direct connection with demineralization, which is probably a function of the skin alone. Whatever the cause and nature may be, the symptoms or consequences of demineralization are manifest: asthenia, fatigue, irritability, etc. Should bronchopneumonia complicate, demineralization reaches its maximum and the patient develops a mixed general and pulmonary cachexia which recalls phthisis. Whether these subjects can be cured by a system of remineralization remains to be seen.

Acidosis and Operation.

It is well known, but the fact is sometimes forgotten, that the existence of acidosis is somewhat of a menace to those who are operated upon. That is, especial care should be taken in the preparation of patients suffering from acidosis who are about to undergo an operation. According to Crile, many postoperative accidents are due to acidosis, which might have been prevented by preoperative measures. In the *Medical Press* of April 9, 1919, Dr. François Tennet, writing on the subject, first gives those symptoms of acidosis to which importance should be attached and then recommends the kind of treatment which is likely to allay the condition and to minimize the dangers of operation. It appears that the lesions associated with acidosis bear on the liver, the cerebral cells, the suprarenal capsules, and the thyroid. Tennet points out that, as a rule, the changes are ephemeral, and that natural sleep brings about repair of these changes; but mere repose, apart from sleep, does not have this restorative effect. Patients soon to be subjected to operation should worry as little as possible, and should sleep as much as possible. Of course, this is Crile's anoci-association teaching, and the interest of it lies in the fact that it is advocated by a French army surgeon, who declares that if the precautions employed by Crile are taken, certain major operations, such as for advanced goiter, gastrointestinal cancer, and operations on the bile channels, may be undertaken with a minimum of risk and a maximum of success.

News of the Week.

Pneumonia in Army Decreases.—During the week ending April 26, there were 5,679 new cases of pneumonia reported among the troops in the United States. This is a marked decrease over the preceding weeks.

The National Health of England.—An analysis of the reports of the medical boards which examined recruits shows that out of every nine men examined only three were fit for service; two were more or less unfit but able to do something; four represented wreckage of one kind or another, some of it hopeless but most of it preventable. The average of fit for the entire country was 36 per cent.; London, 28; Scotland, 44; Wales, 46.

Ten per cent. of the men examined were absolutely unfit for any kind of service.

Typhus Among American Workers in Macedonia.—A report from Kavalla, Macedonia, states more than 600 Greek Refugees from Bulgaria have been stricken with typhus fever and that a number of the Red Cross workers engaged in relief work have died from the disease. A second Red Cross medical unit under Major Samuel J. Walker of Chicago, has been sent to Macedonia, to cooperate with the Greek doctors in combating the spread of the epidemic.

State May Take Over United States Hospitals.—The New York State Hospital Commission is to inspect the United States Naval Hospital at Ward's Island, and the hospitals at Camp Mills and Camp Upton with a view to determining if they can be taken over by the State and used to house insane patients.

Many Army Hospitals to Close.—Surgeon General Ireland has issued orders for the abandonment by June 1 of Debarkation Hospital No. 5 at the Grand Central Palace, the army hospital of the Rockefeller Institute, and Emergency Hospital No. 4, the Polyclinic Hospital, New York. The Hospital at Long Beach, L. I., has also been ordered closed before June 1. In addition to the New York City institutions, those at Hot Springs, Ark., Madison Barracks, New York, and Richmond, Va., have been ordered closed. Nine army hospitals are to be turned over for war risk insurance cases. These are at Camps Beauregard, Louisiana; Cody, New Mexico; Fremont, California; Hancock, Georgia; Joseph E. Johnston, Florida, and Logan, Texas; General Hospital No. 13 at Danville, N. Y., and General Hospital No. 15 at Corpus Christi, Tex. The Base Hospital at Camp Sevier will be transferred to the Public Health Service as soon as the need for its facilities in their present capacity is over. A total reduction of 5,500 beds has been called for at the various camp hospitals.

Memorial Hospital for Soldiers and Sailors.—At the annual meeting of the Grand Lodge of Masons for the State of New York held recently in New York City, it was announced that a memorial hospital would be erected at Utica, N. Y., at a cost of $370,000. The institution will be open to all men of the order who have been in the service and who because of physical debility require maintenance or medical care.

Nurses Get Diplomas.—The Bellevue Hospital Training School for Nurses, New York City, at its recent graduation exercises awarded diplomas to 48 nurses. At the same time 155 received postgraduate certificates. Dr. John W. Brannan, president of Bellevue and the Allied Hospitals, presided at the exercises.

Hotel Opens Hospital.—A fully equipped hospital, with operating room and *x*-ray apparatus, has been opened in connection with the New Hotel Pennsylvania for the use of the 2,000 employees of the hotel. A clinic has been in operation since the hotel was opened a few months ago and treats on an average sixty patients a day. The hospital will be in charge of Dr. Joseph Darwin Nagel.

Hospital Directors and Staff Give Dinner.—The directors of the Hospital for Deformities and Joint Diseases, New York City, recently gave a dinner in honor of Dr. Louis F. Rothschild, the treasurer of the institution, at the Hotel St. Regis. The history of the development of the institution from a very small beginning, in 1894, to its present status as one of the largest orthopedic hospitals in the city was reviewed and it was announced that the directors propose to erect a new hospital building at a cost of $1,000,000 which will afford accommodation for 300 resident patients. Dr. Henry W. Frauenthal is physician and surgeon in chief of the institution.

Dr. William E. Studdiford has been appointed professor of obstetrics and gynecology in the College of Physicians and Surgeons to succeed the late Dr. Edwin Bradford Cragin.

Dr. Henry Monroe Moses has returned from foreign service and has resumed his practice at 108 Prospect Park West, corner Sixth Street, Brooklyn.

Dr. Walter M. Brickner has returned from foreign service and resumed his practice in New York City at 151 Central Park West.

Dr. George W. Crile, who commanded the Lakeside Hospital Unit of Cleveland, which served with the British and French Forces and who later became a consultant of the American Expeditionary Forces, has been cited for the Distinguished Service Cross by General Pershing.

Mayor to Name Drug Committee.—At a recent conference of the heads of the various New York City Departments Mayor Hylan announced that he would appoint a committee within a few days to go over the narcotic drug question with the Federal and State authorities. During the conference Health Commission Royal S. Copeland made the following recommendations for handling the problem: 1. Definition of drug addicts. 2. Registration and identification of drug addicts. 3. Passage of a law making it a misdemeanor for a physician to prescribe drugs for an addict without this identification card or for a druggist to honor a prescription without identification. 4. Passage of a law making it a misdemeanor for the sale of narcotics without a prescription. 5. Regulation by the State Narcotic Commission of amendments to the sanitary code on the subject.

Work of Women's Hospitals in Serbia.—According to a communication from Nish, Serbia, nineteen American women doctors are now in the Balkans, assisting the American Red Cross in its relief work. Among those working in Serbia are Dr. Marjorie Burnham of Ashtabula, Ohio; Dr. Mary H. Elliot of New York; Dr. Harriet M. Gerviais of Dorchester, Mass.; Dr. Marion C. Stevens of Reading, Mass.; and Dr. Regina Flood Keyes of Buffalo, N. Y. Dr. Keyes has just been decorated by the Greek Government for her skill in hospital work both in surgery and in the care of typhus patients. Dr. Catherine M. Cook of Washington, Pa., and Dr. Dora E. Bowman of Kansas City, Mo., are assisting the American Red Cross physicians in Montenegro. Dr. Nell G. W. Bartram of Huntington, Pa.; Dr. Mary J. Hyndman of Philadelphia, and Dr. Sarah E. Foulks of Burlington, N. H., are doing similar work in Albania.

British Cross for Three American Surgeons.—Three officers of the American Army Medical Corps received the British Military Cross from King

George at an investure on May 3. They were Capt. Richard Giles, Capt. D. Murphy, and Capt. F. Stone.

United States Civil Service Examinations.—The United States Civil Service Commission announces open competitive examinations for *medical interne*, for both men and women, to fill a vacancy in St. Elizabeth's Hospital, Washington, D. C., at $900 a year, and future vacancies requiring similar qualifications. The positions are tenable for one year during which a post graduate course in mental and neurological methods is given. At the end of the year examinations are held and promotions made to the next grade, that of junior assistant physician. The examinations will be held on June 4 and July 9, 1919. Applicants should write at once for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C.

Medical Society Elections.—THE GEORGIA MEDICAL ASSOCIATION, at its annual meeting, held in Atlanta, April 19, 1919, elected the following officers for the ensuing year: *President*, Dr. Edward G. Jones of Atlanta; *First Vice-President*, Dr. H. W. Hendrix of Tifton; *Second Vice-President*, Dr. J. M. Smith of Valdosta.

THE GEORGIA PEDIATRIC SOCIETY, at its annual meeting, held in connection with the Georgia Medical Association on April 19, 1919, elected the following officers: *President*, Dr. L. B. Clark of Atlanta; *Vice-President*, Dr. Walker of Macon; *Secretary-Treasurer*, Dr. Anthony Warring of Savannah.

THE HILLSBOROUGH COUNTY (N. H.) MEDICAL SOCIETY, at its annual meeting, held at Nashua, April 17, 1919, elected the following officers for the ensuing year: *President*, Dr. Charles E. Congdon of Nashua; *Vice-President*, Dr. C. O. Colburn of Manchester; *Secretary and Treasurer*, Dr. T. F. Rock of Nashua.

THE LOUISIANA STATE MEDICAL SOCIETY, at its annual meeting, held in Shreveport, April 9-11, 1919, elected the following officers for the ensuing year: *President*, Dr. Amendee Granger of New Orleans; *Vice-President*, Dr. J. A. Gorman of New Orleans; *Secretary and Treasurer*, Dr. C. Barrow of Shreveport.

THE ASSOCIATION OF AMERICAN RAILWAY CHIEF SURGEONS, at its annual meeting held in New York City, May 5 and 6, 1919, elected the following officers: *President*, Dr. C. W. Hopkins of Chicago; *Vice-President*, Dr. Duncan Evans of Nashville, Tenn.; *Secretary and Treasurer*, Dr. Louis J. Mitchell of Chicago.

THE ASSOCIATION OF SURGEONS OF THE SOUTHERN RAILWAY, at its annual meeting, held in New Orleans, April 24, 1919, elected the following officers for the ensuing year: *President*, Dr. H. T. Inge of Mobile; *First Vice-President*, Dr. W. H. Armstrong, Rogerville, Tenn.; *Second Vice-President*, Dr. D. W. Scott of McDonoughville, Ga.; *Third Vice-President*, Dr. A. R. Wolson of Greenboro, N. C.; *Fourth Vice-President*, W. T. Matthews, Greenwood, Miss.; *Secretary and Treasurer*, Miss Edith A. Foltz, Washington, D. C.

Obituary Notes.—Dr. FREDERICK WEISBROD of Brooklyn, a graduate of New York University Medical College, in 1890, died in Philadelphia on May 9, aged 55 years. He was a member of the American Medical Association, a Fellow of the American College of Surgeons, and attending gynecologist to the Wyckoff Avenue Hospital, Brooklyn.

Capt. GEORGE EDWARD HENDERSON, M. C., U. S. Army, of Brooklyn, N. Y., a graduate of the Long Island College Hospital, in 1907, on duty with the 330th Field Artillery, died in France on February 12, aged 34 years.

Lieut. BRADNER EARL GORHAM, M. C., U. S. Army, of Kent, Ohio, a graduate of the Grand Rapids (Mich.) Medical College, in 1903, recently returned from military service, died of pneumonia in the Lakeside Hospital, Cleveland, on March 25, aged 37.

Lieut. WILLIAM WRIGHT WALCOTT, M. C., U. S. Army, of Natick, Mass., a graduate of Harvard University Medical School, in 1905, on duty with the 101st Engineers, American Expeditionary Forces, formerly state inspector of health and later district health officer under the Massachusetts department of Health died in France on March 16.

Lieut. WILLIAM LAFAYETTE COWPER, M. C., U. S. Army, of Michigan, N. D., licensed to practice medicine in North Dakota in 1898, died from pneumonia at a hospital in Liverpool, England, on March 9, aged 43 years.

Lieut. JAMES MADISON GRAHAM, M. C., U. S. Army, of Fruita, Utah, a graduate of the Medical College of Ohio, Cincinnati, in 1902 died in United States General Hospital No. 21, at Denver, Col., from tuberculosis, about April 6, aged 40 years.

Dr. NORMUS PAIGE died at his home in Taunton, Mass., on April 15, aged 79 years. He was a graduate of the Medical Department of Dartmouth College, in 1861, an ex-president of the Massachusetts Medical Society, for twenty-five years physician of the Bristol County jail, and a member of the staff of the Morton Hospital.

Dr. JOSEPH MERZBACH, a graduate of the Long Island College Hospital, in 1883, attending physician to the Jewish Hospital, and chief gastroenterologist to the Jewish Dispensary, died of heart disease at his home in Brooklyn on April 28, aged 62 years.

Dr. HENRY CLAY WILBUR of Pine Plains, N. Y., a graduate of Bellevue Hospital Medical College, in 1867, died in Brooklyn, N. Y., on May 6, aged 75 years.

Dr. WILLIAM HENRY HALE, a graduate of Yale University Medical School, formerly superintendent of the Baths of Brooklyn, and one of the founders of the American Association for Promoting Hygiene and Public Baths, died on May 3, at the age of 78 years.

Dr. NATHANIEL GARLAND KEIRLE died, after a long illness, at his home in Baltimore, on May 2, aged 86 years. He was a graduate of the University of Maryland Medical School, and was for 30 years post-mortem physician of Baltimore. He lectured in pathology at the College of Physicians and Surgeons, Baltimore, from 1881 to 1892, and occupied other positions on the faculty of that institution.

Dr. EMMETT V. BALL, a graduate of the Georgia College of Eclectic Medicine and Surgery, in 1894, and a member of the faculty of that institution, died at his home in Atlanta of heart disease, on April 23, aged 49 years.

Correspondence.

THE MEETING OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

To the Editor of the Medical Record:

Sir:—Although the meeting of the Medical Society of the State of New York, on May 6, at Syracuse, was one of the most important of these events in recent years, no mention of its proceedings was given in any of the New York newspapers.

Considering the prominence of compulsory health insurance as a political issue in this State, the fact that the delegates of the society to the American Medical Association meeting, next month, were instructed to oppose this measure in every way was a matter of news worthy of mention, even though the expression on the subject was contrary to the views of the New York press in general.

Another important event was the appearance of Senator Davenport before the House of Delegates. This took place before the election of the president of the State Society, one of the candidates for which office stood avowedly upon an anti-compulsory health insurance platform. The appearance of Senator Davenport was upon the invitation of the president of the society, and was the cause of considerable adverse comment. It led to the introduction and passage of a resolution that no one hereafter should be invited to address the House of Delegates unless invited to do so by the society itself. A request of a most unusual character was made of the society after the members had finally concluded to permit Senator Davenport to address them. This was made by the chairman of the legislative committee of the Medical Society of the County of New York. It was to the effect that the Senator was to be heard without question, interruption, or mark of disapproval. Evidently the mover of this motion did not realize the difference existing between the temper and amenities of a representative body of medical men and those of a miscellaneous aggregation of opponents to a political measure of this kind at a hearing before the Legislature at Albany. One of the reasons given during the discussion for allowing Senator Davenport to address the society was that he would do his cause no good by his argument in its favor. This proved to be correct, inasmuch as his sole plea for compulsory health insurance was that it offered a means to combat the rising spirit of Bolshevism among the working classes in America by ministering to them in sickness and disease, and thus getting them to realize that the politician was the modern representative of the "good Samaritan," no matter to what political party he belonged.

This appropriation of the time-honored distinction and reward of the profession of medicine, as embodied in the Biblical character in whom is personified our mission, was not accompanied by any proof whatever that lack of medical service to the poor in Russia in any way figured among the causes of this lapse into anarchy, under the guise of socialism, by this once great and powerful people.

A measure to establish a commission for the purpose of protecting the profession from adverse legislation at Albany was proposed and pressed for adoption. The composition of this body was severely criticised. It was claimed that it would be controlled by the members selected from among the Public Health Committee of the New York Academy of Medicine, from which source the funds and the active management would also proceed. It was shown, as well, that from this body had arisen the various plans for compulsory health insurance in this State, which the society was now united in opposing. The matter was not put to a decisive vote on its merits, but was left over for action by the Council of the Society in the fall.

A most astonishing proposition was one to exclude every person from the meeting of the House of Delegates during its session except the delegates themselves. The delegate making this proposition claimed that the presence of visitors invaded a privacy that was semi-sacred in character. It prevented, or at least interfered with, cerebration relating to matters of medical legislation of a family nature. He was voted down as verging upon madness of a stark, staring kind, which would make the Medical Society of the State of New York an anomaly among legislative bodies of a deliberative character everywhere.

The project for annual registration of physicians was approved with but one dissenting vote. The result of this will be to place the burden of opposing this measure on medical men and medical bodies not affiliated with the State Medical Society. It was supported by the chairman of the legislative committee of the State Society. The chief reasons given were that "somewhere in this State" diplomas of deceased doctors were offered for sale, and that their purchasers were practising medicine under them; also that the dentists and veterinarians were registered, and did not object to this measure. It was stated, as well, that local district attorneys will not prosecute illegal practitioners, and that the attorney general, to whom this duty will attach, will have no such scruples in the matter as his deputies in the rural districts. It should not be overlooked that those who are responsible for this form of registration are also advocates of periodical examinations of physicians, of which the registration bill is the entering wedge. It also accords with the new political dispensation which demands the registration with the police of every one who can be brought within the purview of the State. This form of "measuring and mugging," figuratively speaking, was advocated in laws before the last Legislature for any one renting a room to a lodger in this city or for any one "suspected" of having venereal disease.

John P. Davin, M.D.

OUR LONDON LETTER

(From Our Own Correspondent.)

London, April 16, 1919.

The Special Clinical Meeting of the British Medical Association.—The special clinical meeting of the British Medical Association, whose activities came to an end last week, was an unqualified success, scientific and social. A well devised piece of statesmanship on the part of the authorities of the association led them to hold this meeting in lieu of the autumn scientific and social gathering, for such an autumn meeting of the accepted type would not have taken advantage of the opportuni-

ties now present in London, owing to the sojourn in or near the metropolis of so many representatives of the medical department of the American Army and of the British Dominion Forces. The special idea of the meeting was to bring these learned and gallant of our colleagues into personal relations with the medical profession of the home country, to gather from their experiences, and to make the medium of interchange between the Dominions and ourselves for the lessons learnt at the war. The meeting was carried out in exactly this spirit, and because it was not over large it gained its particular efficiency. Many people who had met before met again, resumed their friendships, revised their opinions of each other, and interchanged views, and projects without the stiffness inseparable from recent introduction. Moreover, as it happens, there are large questions, of medical education and medical reform generally, on the lips and in the minds of the medical profession at home, and these supplied endless topics for discussion, apart from the actual business of the special meeting, upon subjects which cannot be looked at from too many points of view, and whose consideration should always be revised by as much intimate knowledge as can be obtained of the different circumstances in which medical men carry on their work. From these discussions many of us have received liberal instruction in sociology at many pleasant reunions.

Among these reunions may be mentioned first, the reception of the congressists at the Guildhall, the beautiful medieval building which is the center of the City of London Municipal Government, as distinct from the London County Council. Among the guests received here by Sir Clifford Allbutt were many members of the American Medical Service who were notable alike for the interest which they took in the lectures and illustrations of London life from the Roman times downwards and for the energy with which they danced, for an impromptu feature of the function was a dance. On one afternoon the President of the Royal College of Physicians was at home in Pall Mall to members of the Congress, when the unique collection of books, manuscripts and pictures in the possession of the college was on exhibition under the learned direction of the President, Dr. Norman Moore. On another afternoon the President of the Royal College of Surgeons of England, Sir George Makins, entertained the congressists at an exhibition of the Hunterian and Listerian relics possessed by the college in Lincoln's New Fields. The whole Hunterian Museum of the college was opened to the inspection of the guests. Sir Clifford Allbutt entertained certain of the prominent organizers of the meeting to dinner at that home of Bishops, Judges and Professors, The Athenæum, and on the same evening the guests proceeded to join the Congress assembled later at the Royal Society of Medicine, where a reception was given by the President, Sir Humphry Rolleston. On the last day of the Congress the editor of *The Lancet* entertained at luncheon the representatives of the American and Overseas Forces, the office-bearers of the Congress, and others connected officially with British Medicine. At all these functions real cordiality and good-fellowship prevailed and it is impossible that there should not follow from so much close interchange of ideas good results for medicine.

The Local Government Board and the Housing of the Poor.—One of the first acts to be undertaken by the Government must be to improve the housing conditions of the county. New houses were wanted for the industrial classes all over the kingdom even before the war, and no building has been undertaken, save in the direction of temporary hospitals, munition and other factories, aerodromes and accommodation railway stations since the autumn of 1914. The country is probably 400,000 houses short, while many that are still inhabiteed are from the medical point of view uninhabitable. A Housing and Townplanning Bill is before the House of Commons at the present moment, and under it local authorities, who are local and popularly elected committees entrusted to carry out the essentials of local government, will be required to supply information to the Local Government Board as to the number of houses needed in their districts, and the proposed building scheme to meet the need. It is necessary that the local authorities should consider their action well and have their plans cut and dried so that no time may be wasted, and that building and reconstruction can take place the moment the Housing and Townplanning Bill becomes law. Therefore the Local Government Board has just issued a valuable memorandum for their guidance in drawing up such schemes, from which information can be drawn upon such essential matters as the choice of site, the method of drainage, the laying down of roads and the building of houses combining sanitary virtues and some measure of comeliness with economy. Local authorities whose schemes find favor with the Local Government Board will receive state grants, in aid of their activities.

The Late Dr. A. G. Bateman.—Dr. A. G. Bateman whose death was announced this week was one of the best known medical men in the country because of the nature of his occupation and the brilliant way in which he discharged its duties. He was the secretary of the Medical Defense Union, an association of medical men for their mutual protection in legal difficulties, which took notice also of infringements of the law where these offenses were especially to the detriment of the medical profession. Thus a doctor threatened by a disgruntled patient with an action for malpraxis, or by a mean patient with a refusal of his fees on the ground of exorbitant charges, or by some salacious or blackmailing woman with a charge of assault, can go straight to the Medical Defense Union, if he is prudent enough to be a subscriber, and cast his burdens upon the association. Bateman received all such cases with learning and enthusiasm. A barrister as well as a doctor, and in his time a coroner, he was versed in all the methods of the cheat and the blackmailer, and seldom indeed did any action succeed against any of his clients. Quacks and unqualified practitioners feared his name also, for he was quick to detect where their habits of charlatanry became illegal and ruthless in tracking the of-

fenders down, haling them before justice, and exacting the fine. Bateman raised the Medical Defense Union from a small organization to a really powerful affair—he lived for his work and reveled in it. His industry and enthusiasm were all the more creditable to him that he had exceedingly bad health; but the idea of living like a vegetable in order to prolong his days made no appeal to him, and he died, full of zeal and full of work, suddenly in his sixty-sixth year.

Some Revelations of War Records.—The statistics of the recruiting medical board have before now been referred to in these letters as revealing deplorable facts in the physique of the manhood of the country, and the *Times* has published today some figures for which they do not claim official support but which they assert are yet sufficiently accurate for practical purposes: Out of every nine men examined, three were fit for service and were good lives; two were more or less unfit, but able to do something; four represented wreckage of one kind or another, some of it hopeless, most of it preventable. The picture for the whole of the country will, we believe, be found to average out something after this fashion: Fit men, 36 per cent.; fairly good men, 23 per cent.; unsound men, 31 per cent.; totally incapacitated, 10 per cent. Put in that way the record is dismal indeed, but the recruiting boards had not to take cognizance at all of all that great mass of healthy manhood that joined the war in the first rush. From the medical point of view, however, dismal records of this sort have their value, for they frighten the public into giving money for the many medical agencies necessary to counteract such a state of affairs. London is believed to come particularly badly out of the statistical ordeal; London is not an over generous city, considering its size, wealth, and prestige toward the causes of medicine and medical research, and a scare as to the physique of its inhabitants may open hearts and also purses.

1. Early Recognition of Carcinoma of the Stomach.—John B. Deaver refers to the difficulty of diagnosis in cases of cancer of the stomach, a difficulty rendered all the greater in the absence of a reliable test for early cancer. The medical man should therefore consult the surgeon in all cases at the so-called cancer age (35 to 45 years), presenting a history of symptoms which suggest this disease. One of the frequent findings at operation, or postmortem, is evidence of healed ulceration—described by Smithies as the "tabloid" type. In such cases the mistake often lies in treating the symptoms instead of the cause. In the majority of cases the clinical history is that of gastric ulcer—periodical attacks of dyspepsia, with generally good health between the attacks. These cases, if taken in time, need never have developed cancer. In other cases, in which cancer is grafted on an ulcer of atypical type, where the history could be construed as chronic appendicitis, chronic cholecystitis, or chronic pancreatitis, early diagnosis is impossible; the only salvation offered is in opening the abdomen, inspecting and feeling. The skillful employment of the *x*-ray or fluoroscope is the next approach to diagnosis, but even so the findings may be none other than distortion of the duodenum, a shadow in the gall-bladder region, delayed passage of the bismuth meal, or the presence of adhesions. In these cases the treatment indicated is medical, but this should not be persisted in if the condition does not yield promptly and give reasonable evidence of permanent cure. Since one-half, or more, cases of gastric cancer follow on ulcers, the treatment of early carcinoma depends largely upon the early recognition and treatment of gastric ulcers. Although a good deal of reliance is placed on gastric analysis in the diagnosis of cancer, Deaver points out that in early carcinoma there is no actual rule as to the acidity of the stomach contents. High acidity is often noted in gastric ulcer; this, acting as an irritant, particularly on the edges of the ulcer, produces changes in the glandular cells, which are probably the first step in carcinomatous proliferation. High acidity is therefore not necessarily ruled out, especially when located on the anterior wall of the stomach, involving the greater curvature where it is likely to cause only slight disturbance of motor function. On the other hand, hypochlorhydria or the absence of hydrochloric acid, which is generally considered pathognomonic of cancer of the stomach, is associated with about 30 per cent. of cases of gallstone disease and also about the same percentage of other conditions, such as pancreatitis, diabetes, renal calculus, etc., so that a low hydrochloric acid, or absence of this acid, furnishes evidence but no proof of cancer. Nor is the presence of lactic acid and the Boas-Oppler bacillus proof positive, since lactic acid is frequently, and the Boas-Oppler bacillus occasionally, associated with benign dilatation of the stomach. When the case has advanced to the stage of permitting recovery of the Boas-Oppler bacillus, surgery promises little or nothing. Detection of pus by the microscope and the presence of occult blood may be of diagnostic value, but they are not always demonstrable in early cancer. None of the tests devised have proved specific in diagnosis, and this is also true of *x*-ray and fluoroscopic evidence. Their importance rests on their demonstration of a surgical condition in the stomach, but not on their power of differentiating the condition. In the last analysis, therefore, we come to history and exploration, which are the most reliable sources of information. A patient in middle life giving a history of gastric ulcer, or one who has always enjoyed good health until about a year or six months ago, and now complains of gastric symptoms, epigastric pain, with more or less rigidity, progressive loss of weight, strength and appetite, with or without vomiting, with more or less motor insufficiency, hydrochloric acid increased, moderately diminished or entirely wanting, lactic acid and Boas-Oppler bacillus present or absent, justifies a tentative diagnosis of cancer. The *x*-ray in such cases will probably show some changes in the outline of the stomach and anomalies in the peristaltic waves, but laparotomy and the pathological laboratory will give definite information which will enable the surgeon to act, giving the patient a promissory note for relief if not for a permanent cure. What William J. Mayo wrote in 1904 still holds good: "In an early exploratory incision we have the one diagnostic resource which is reliable, and which must be resorted to in a large majority of cases before a surgical diagnosis can be made. Without it the truth is but slowly established at the expense of progressive hopeless involvement. Exploration can be safely accomplished through a small incision and with a short time of disability. It is said that the patient will not submit to an abdominal incision upon suspicion. Herein we do the intelligence of the public an injustice; we have seldom been refused the opportunity, when the matter has been fairly and candidly laid before the patient and his

friends. The plea for delay has more often come from the attending physician."

1. The Value of Biological Principles in Surgical Practice.—J. Shelton Horsley points out that surgery is more a science than an art, and that the science of anatomy is essential to the mechanics of surgery. A surgeon who is a dexterous operator and who skillfully amputates a leg that with patience and scientific application could be saved is merely a good artisan and is distinctly inferior to the surgeon who could save the leg even though he should be a bungling operator. The principles underlying an operation are correct only if they conform to the laws of physiology and of repair of the tissue or organ that is affected. If we could get away from blindly following what someone says and do things because of reasons that have sound biologic foundations, the results would be more satisfactory. Speaking of hyperemia, Horsley likens the methods of procedure formerly in vogue to the situation described in the old poem about the four blind men who went to see the elephant. Each was partly right in what they saw, or rather felt, but their conclusions were wrong. In connection with the treatment of slow or threatened gangrene, Carrel and Guthrie, after two experiments, concluded that the blood circulating in the leg of a dog could be completely reversed within six hours. Further experiments, however, showed that there was no real reversal; what happened was that dissection paralyzed the vasoconstrictor nerves, and the dilated capillaries permitted red arterial blood to flow through unchanged. Many useless operations have been done attempting so-called reversal of the circulation in threatened gangrene. The only good accomplished was damming back the venous blood and forcing the small amount of arterial blood that reached the tissues to stay longer than it normally would and so deliver to the tissues more nutrition; this can be simply effected by ligating the femoral vein. Surgery of the gastrointestinal tract suffers from the lack of application of physiological principles. For instance, the popular operation of gastroenterostomy does relieve the symptoms of many patients with duodenal or gastric ulcer. The unfortunate minority, however, still have their symptoms, and the restoration of normal channels by undoing a gastroenterostomy is not infrequently brought about. The cures have never been fully explained. Some say gastroenterostomy is a drainage operation, and yet in draining other hollow viscera they are not opened at the lowest point. Others say that the operating cures because the acidity of the gastric juice is lessened, and still others assert that by short-circuiting the course of food, rest is given the ulcer. Roentgenoscopy, however, reveals that unless the pylorus is closed a considerable portion of food continues to go by this route, and no pyloric closure seems to be permanent unless a resection is made. Recent physiological research has shown that the character of the gastric juice has nothing to do with hunger pains, except in so far as it excites an abnormal amount of peristalsis. Food or sodium bicarbonate lessens peristalsis and so relieves pain. Recent investigation seems to show that the stomach has a limited supply of nerves that conduct pain, and that these nerves are rendered abnormally sensitive by the inflammation around an ulcer. Gastroenterostomy probably relieves pain by facilitating the emptying of the stomach and so lessening peristalsis. This being so, it is the treatment of a symptom and not an effort to remove a pathological condition. The work of Cannon and Murphy in their studies of peristalsis after resection of the bowel has not received proper attention. Lateral anastomosis practically abolishes peristalsis in the region of the anastomosis and food can be pushed through only where a column of it extends into a proximal loop where peristalsis is unimpaired. Postmortems in dogs have always revealed an accumulation of food at the site of the lateral anastomosis. With attention to the triangular mesenteric spaces and careful closure of these and of other raw surfaces before the bowel is opened, together with disinfection of the bowel ends after opening, equally good technical results are obtained in end-to-end union, with the advantage of securing normal peristalsis and normal emptying. One of the common problems of surgery, and a most interesting one, is surgical drainage, which really depends upon a reversal of the circulation in the local lymphatics and is chiefly a biological process. It is nature's effort to extrude a foreign substance. In drainage of the abdominal cavity, where there is an enormous lymph space and where lymph is enormously poured out, the drainage tube causes an immense flow of lymph that carries through the tube much of the septic products that would otherwise have been absorbed. Drainage prevents positive pressure in the suppurating cavity and at the same time has the equally important function of being a stimulus for the reversal of the lymphatic circulation. When a wound is packed with gauze, the gauze acts as a foreign body and lymph is poured out into the gauze in an effort to wash it away. In portions of the body where lymph is not so abundant, drainage must be dependent. The cigarette drain is an exciting cause for reversal of the lymph circulation, a fact which explains its beneficial action. In neurological and bone surgery metal screws and steel plates have been used, with the result that nature, in an effort to expel these foreign bodies, causes an absorption of lime salts, the bone softens, and the screw becomes loose. Furthermore, osteoporosis is induced and callus formation is prevented or retarded. In certain cases of surgery the effect of the emotions is of the greatest importance; for instance, fear or excitement in exophthalmic goiter. Again, skin grafting and the transplantation of organs or tissues are dependent on biological laws; skin grafts from others than the patient are practically never permanent, and the transplantation of highly developed organs, such as a kidney, from one animal to another, even if of the same species, is always a failure. Real progress in surgery, therefore, lies not so much in cultivating the art of surgery and in striving after mechanical dexterity as in the study of biological principles which concern function, metabolism, and repair of tissues, and in the thoughtful application of these principles to every operation and to every method of surgical treatment.

3. The Treatment of General Paralysis of the Insane by the Introduction of Salvarsanized Serum into the Lateral Ventricle and a Suggestion for the Arrest of Tabetic Optic Atrophy by the Same Means.—Harry Campbell and Sir Charles Ballance refer to papers published by each of the authors in the *Lancet* for May 30, 1914, which were based on three cases of general paralysis of the insane in which salvarsanized serum was introduced into the lateral ventricle. As one of the patients in question is still alive five years after the first treatment (the serum was introduced on two separate occasions, at short intervals) and has been able to return to his profession of violin playing in a London orchestra, the authors believe that there are

grounds for holding that the treatment did arrest the disease and restore the patient to such a state that he could earn his living. These authors point out that it is known that the *Treponema pallidum* is very sensitive to the antibodies in the blood and to remedies which probably have a direct action on it. The object, then, is to introduce salvarsanized serum into the cranial cavity in such a way as will admit of the serum coming into contact, by the shortest route, with the brain cells which are in danger of destruction by the syphilitic virus. The essential points are that the serum should circulate in the perineurotic spaces of the brain where the spirochetes reside, and that more salvarsanized serum can be inveigled into these spaces by the intraventricular method than by any other. The method proposed can only be fully effective in the very earliest stage of the disease before extensive damage has been done to the nerve cells. The pre-clinical stage of syphilitic brain disease is therefore the ideal time, and here investigation of the cerebrospinal fluid affords valuable help. In this connection the authors draw attention to the following facts: So long as the central nervous system is not infected by the spirochete, giving rise to interstitial or parenchymatous syphilis, the cerebrospinal fluid gives a negative Wassermann reaction, owing to the fact that the capillaries of the central nervous system (those of the choroid plexus among others) are impermeable to the Wassermann substance. It is quite common to get a positive blood reaction and a negative cerebrospinal fluid reaction. A positive reaction of the cerebrospinal fluid is thus proof positive that the central nervous system is infected with the spirochete. When the cerebrospinal fluid gives a positive reaction the blood generally does so too. This is as we should expect, seeing that the fluid drains off into the general blood-stream. In rare cases, however, the blood reaction is negative when that of the fluid is positive. In general paralysis both the fluid and the blood give a positive reaction in practically every case. If we find the blood negative the chances are nearly 100 to 1 that we have not to deal with a case of general paralysis, but if there is any doubt the fluid should be examined, since in very rare cases of general paralysis the fluid may give a positive reaction, while that of the blood is negative. In the case of interstitial syphilis of the nervous system we may hope to render a positive reaction of the fluid negative by administering mercury and the salvarsan group of remedies through the blood. In the case of parenchymatous syphilis of the central neurons this is much more difficult; with general paralysis it is impossible. By introducing salvarsanized serum into the spinal subarachnoid space a positive reaction of the fluid can be rendered negative in the case of tabes dorsalis. By introducing the serum into the cerebral ventricles we may hope for a similar result in general paralysis. The authors suggest that the same method might be employed to arrest tabetic nerve atrophy, but whether the injection should be made into the lateral ventricle or through the outer angle of the sphenoidal fissure into the subarachnoid space at the base of the brain remains to be determined. They add that the demobilization of the army and the probable increase of syphilis make it highly desirable that any means which may have a remedial influence on syphilitic infections of the nervous system should receive careful study.

3. Discussion on Gunshot Wounds of the Chest.—Colonel T. R. Elliott comments on the necessity for more knowledge of the physiological and pathological changes associated with the gross objective features of chest wounds and the importance of collecting and preserving all available observations and clinical notes on this subject. He points out that, on account of its elasticity, the lung tissue, though infected with blood, does not fissure and rarely shows contrecoup injury at a distance from the wound and that the changes in the pulmonary circulation are probably only those associated mechanically with the hemothorax. On the other hand, the muscular coat which envelops the bronchial airway can be directly relaxed or constricted by nervous impulses; in the guinea-pig the injection of egg-white will cause death by sheer asphyxia, and in goats strong constrictions of the bronchiole muscles occur upon exposure to phosgene or chlorine gas. In man the physiological activity of the muscle is obscure, but it may be that its main purpose is to protect the elastic tissues of the air sacs from harmful overdistension. Assuming that the musculature is thrown into strong contraction throughout the lungs as the usual reflex reaction to a chest wound, cyanosis and dyspnea result, both of which disappear as a rule with rest and the administration of morphine. Occasionally, however, these conditions persist and experience has shown that such patients stand an operation badly. It is fair to assume that the condition is caused by a prolonged reflex constriction of the bronchiolar musculature, which damps down the air current. In this case the lung would remain virtually inelastic and instead of being sucked out by inspiration, the intercostal space would conversely be sucked in, a phenomenon which is actually seen to occur. After a chest wound, respiration is shallow and quickened, with a small air current. On the injured side the intercostal muscles are said to show an increased tone, "guarding the wound within," while their respiratory rhythm is often lessened almost to complete immobility. The rhythmic movements of the diaphragm are also lessened, but the tone of the muscle does not seem to be increased, for the *x*-rays a few hours after the wound show that it is in a position of extreme elevation, that is, of relaxation in the complete expiratory phase. The outstanding characteristics of a hemothorax are the elevation of the diaphragm, the small size of the chest, and the tendency to partial or complete collapse in any area; while later the part of the lung on the wounded side which is not submerged in the hemothorax shows an unusual compensatory emphysema. The lung tends to be small on the wounded side and to collapse everywhere. Sir John Rose Bradford has explained these characteristics by assigning them to an external compression caused by the retraction of the chest wall and the immobility of the diaphragm in an extreme expiratory phase. The smallness of the lung, however, might equally be explained by an associated constriction of the bronchiole muscles, cutting off the diminished air current from the alveoli. The diminution of the air current, which results from the lessened inspiratory activity of the external muscles of respiration, must also be recognized as of importance; otherwise the lung might be overdistended as in the case of the guinea-pig's death from anaphylaxis. When once these conditions are established, the air in the air sacs—nitrogen as well as oxygen—is rapidly absorbed into the circulation and large areas of the lung may be completely deflated. General massive collapse of the lung on either side is rare, its only practical importance being that it is a contraindication to operation. Smaller areas of collapse do occur, but not in the frequency claimed by some writers. Such collapse is seen most often in a triangular area occupying the middle sector of the lower lobe, with the base of the triangle resting on the diaphragm. Such a distribution must be determined by some factor within the lung itself, and dissection has proved it to be due to the fact that the main bronchus of the lower lobe divides into three branches which do not communicate with each other, the middle one supplying the middle triangular sector. This bronchus is crossed at right angles by the great branch of the pulmonary vein which runs forward from the back of the lower lobe to join the main trunk at the lung's root, no lung tissue intervening between the vein and the bronchus. These conditions were reproduced in a case of phosgene gas poisoning described by the author. The main pulmonary artery on one side was greatly obstructed by a thrombus on its inner wall, so that the vessels in the contralateral lung must have been engorged just as with a hemothorax. Thick mucopurulent secretion half blocked the bronchus. Consequently, the airway at this critical

anatomical point was closed and collapse ensued. The result of this chance anatomical relationship is analogous to that with intratentorial tumors of the brain. Its chief importance lies in its reference to the general theory of collapse. Colonel Elliott holds the view of a general reflex bronchiolar constriction, which prepares the lung for collapse when the external respiratory movements are inadequate; a theory which may also explain the excessive emphysema. Further information, however, is needed, with observations on the presence or absence of early cyanosis, on the precise activities of the thoracic muscles of the diaphragm in early hours, especially in cases which felt "winded" after their wound. Knowledge of the action of the bronchiole muscles is much needed for general medicine and it is important that surgeons should bring forward their own observations to decide whether the hypothesis outlined above is true or false. It should be remembered that all reflex conditions are liable to rapid alteration when the thorax is freely opened by the surgeon. Were this knowledge available, it might be possible to control by drugs such a bronchiole constriction and thus bring dangerous cases within the reach of a successful operation. In regard to hemothorax, the view put forward by Henry and the author is generally accepted; that the effused blood very rapidly passes through the clotting process, but that the coagulation is interfered with by the respiratory movements so that the fibrin is to a considerable extent whipped out of the blood. Very rarely does an entire massive clot form. Sometimes the fibrin is completely separated, leaving a fluid blood, red, non-coagulable, and full of corpuscles. Usually the process is of an intermediate type, and lumps of jellied clot are deposited on the pleural surfaces or lie away in the pleural recesses. The pleural membranes then react by mild inflammation to some constituent of the hemothorax, even when it is sterile. There is an outpouring of pleural effusion containing more fibrinogen, and the clot on the lung surface is thickened and organized. The fluid mixture can be withdrawn by aspiration; the clot cannot. In process of time, the hemothorax develops into a tough jacket which restricts the lung to the size at which it is for the moment confined, and hinders subsequent expansion when the fluid is removed. When the hemothorax is chiefly fluid, with little clot, early aspiration will suffice and the lung expands almost at once. In the case of a large hemothorax—considering the hemothorax in itself only—early aspiration must be the routine; and if this should fail by reason of the clot, the chest must be evacuated at the earliest possible date by thoracotomy without drainage. During the war, however, the problem has been the checking of the spread of infection (50 per cent. of the cases of septic hemothorax died). The thoracic wall is now closed and repaired by early operation and infection is thus prevented from creeping inwards to the pleural cavity. Moreover, the surgeon now opens the wound and removes infected material lying within the hemothorax.

4. Surgical Aspects.—Colonel G. E. Gask points out that the great lesson that has been learned in this war is a clear conception of the biology or evolution of a wound. Nearly 100 per cent. of all wounds are contaminated, a period of some hours elapsing between contamination and infection, that is, before the organisms have had time to multiply and invade the tissues. Antiseptics are of little value. The wound should be excised in the latent period between contamination and infection, and foreign bodies removed. The wound should then be closed and the patient kept at rest. If this can be done, much needless death, suffering, and disability can be saved. The advance in thoracic surgery is due to the application of these principles to gunshot wounds of the chest. Fatalities from chest wounds fall into three main groups: (1) Deaths a few hours after admission to a casualty clearing station, usually due to extensive and severe injuries with loss of blood and shock. Few only of these cases can be saved, but the percentage has been improved with the aid of better resuscitation methods and blood transfusion. (2) Deaths two or three days after the injury, due to sepsis of the pleural cavity and its contents. (3) Deaths at the base, invariably due to sepsis. Treatment must therefore be directed towards elimination of infection. The pleural cavity may be contaminated: (1) By the missile or portions of clothing or equipment carried in with it; indriven splinters of rib are a factor both of causing and maintaining sepsis. (2) Through the wound of the chest wall. A wound which leads directly into the pleural cavity and through which air is sucked at every breath will always lead to infection. Even a small wound, through which air is not being sucked, unless cleansed by operation, may suppurate in the course of a few days, and unless the thoracic cavity has become sealed off by natural means organisms pass through into the pleural cavity, where they find the hemothorax fluid a good breeding ground. (3) From the wound of the lung itself in which the missile, bone, or piece of cloth may be retained. The duty of the surgeon is (a) to arrest hemorrhage; (b) resuscitate collapsed cases; (c) when required, to cleanse the wound of the chest mechanically. Chest wounds present themselves to the surgeon in the following categories: Perforating or through-and-through bullet wound; perforating or through-and-through shell wound; penetrating wound with retention of large missile; penetrating wound with retention of small missile; open thorax; tangential parietal wound; thoracic wounds complicated by injury of the abdomen or spine or by multiple wounds. Clinical appearances are initial distress and hemoptysis. Principles of treatment are considered by the author under physical examination, x-ray examination, and resuscitation. The indications for early operation are: A ragged wound of the soft parts; compound fracture of the ribs; continued bleeding, whether from the inside or out; suction of air into the pleural cavity (open thorax); retention of a large foreign body; pain—out of proportion of the apparent severity of the injury (often the result of indriven splinters of bone scratching the lung with every respiratory movement); rapidly increasing pneumothorax (valve pneumothorax). The skillful administration is of more importance than the kind of anesthetic employed. At operation, the objects to be aimed at are: Excision of the wounds of the soft parts; excision of the broken bones—ribs or scapula; cleansing of the pleural cavity from blood, missile, indriven fragments of bone, or clothing; excision (when possible) of the damaged area of lung; suture of lung; closure of the thoracic cavity. If a careful and complete operation is performed, no special after-treatment is required as a rule; care must be taken, however, that no accumulation of fluid takes place in the pleural cavity and, to this end, systematic needling is advocated. In injuries involving both chest and abdomen, the abdominal viscera may herniate into the pleural cavity, a complication more frequent on the left side because of the protection of the liver. As efficient repair of the diaphragm can only be obtained from above, it is better to open the chest first, replace the abdominal contents, suture the diaphragm, and deal with the chest as already indicated, and then, if there is evidence of injury to hollow viscera, laparotomy may be performed. Similarly with multiple injuries involving both chest and abdomen, it is probably better to deal with the abdominal injury first, but when the patient's condition allows, the chest wound should be treated, even if only to excise the parietal wound. In the treatment of hemothorax, as soon as infection is proved or suspected, it is essential to empty the chest of all infected blood and clot. This cannot be done by aspiration and must be done by open operation. The common practice has been resection of one inch of rib and insertion of a tube. Provided that operation is done within a few days of receipt of the wound, it is better to do a wider resection, removing all clot and washing the pleural cavity. The chest should then be closed. The method offers the following advantages: The chest may remain closed, the organisms not developing; the lung is allowed to expand and adhesions may form which will prevent complete collapse, even if the pleural cavity is subsequently drained; respiratory distress is much less with the closed chest. Drainage of the chest the author considers in the same light as amputation of a limb; it is sometimes necessary to save life but still a surgical failure. Commenting on the lessons learnt in military surgery, which may be applied to civilian practice, Colonel Gask draws atten-

tion to the following points: (1) The treatment of crushed or "stove in" chests. These cases occur in civilian practice. When associated with severe laceration of the lung by indriven fragments of bone, thoracotomy may be of service. (2) The author has discussed the advisability of thoracotomy for the cure of intrathoracic carcinoma of the esophagus with Dr. Meyer, and cites the urgent warning of the latter, that the condition of patients wasted with disease renders them much more dangerous subjects for thoracotomy than the vigorous soldiers operated on in France. (3) In regard to improving the treatment of empyema he is more hopeful. He suggests that in certain cases, particularly of children with a pneumococcal empyema, the pleural cavity may be washed out and the chest closed without the use of a drainage tube. This method has been performed successfully and may be beneficial in suitable picked cases.

1 An Open Letter to the Medical Profession. Eli G. Jones.
2. The Value of the "No-Good" Goiter. Douglas H. Stewart.
3. Preventive Medicine or Hygiene. E. Stuver.
4. Prolapse of the Rectum. Charles I. Drueck.

2. Goiter.—Douglas H. Stewart emphasizes the fact that there are exceptions to every rule formulated so far as goiter is concerned. With regard to the influence of water on the origin and development of goiter, one point stands out, namely, that the drinking of certain water is so much a factor that women have the trouble more than men, because they drink more water. Goiter-producing water often contains lime and iron. Much has been made of this, though the fact that the water from goiter-producing wells may be drunk with impunity, if it be previously and thoroughly boiled, rather militates against the idea of the cause being anything of a mineral nature. Good reports were made at one time concerning the value of the addition of iodine to water. Much was expected of it, but thyroid administration has rather pushed that considerably into the background. The usual test of a goiter is to ascertain whether it rises or falls during the act of swallowing, and if it move with that act then it is to be considered a goiter. The matter of position is rather baffling to a beginner, when he hears some glandular swelling called goiter, yet it is at once evident that the glandular involvement may be in some such gland as the submaxillary. Or it may even be found within the larynx or trachea. It must be remembered that the thyroid has a way of having accessory thyroids pretty much anywhere about the neck, and as the gland itself and these accessories have no ducts, it is very likely that an accessory thyroid could be placed almost anywhere and could yet function perfectly, so that he only who would insist that a goiter must be near or alongside the larynx or treachea, would be the only one who could be deceived by a goiter in some unusual position. The prognosis of goiter is favorable. The simplest method of cure, and perhaps the fundamental one, is to see that the goiter-producing substance is not present in the water. For, if the goiter is once started, a very little of the unknown substance will make certain that goiter's growth. As for treatment, whether it be medical or surgical, it is very possible that the success or failure of that treatment may turn on the question as to whether the patient drinks plain or boiled water. A surgeon may remove a goiter, may do so well and skillfully, but he may have trouble later with some such form as recurrent goiter, that the drinking of boiled water might have forestalled. Boiled water is not the unpalatable thing that it is taken to be if it is only put into a bottle and well shaken so that air is well mixed anew with the fluid, to replace that driven out by the process of boiling. It is very curious indeed to note that the North American Indian was almost exempt from goiter, even though it affected the white man who followed him in the occupation of the same lands. Nor is it less strange that along the Yser River goiter is endemic along the left bank, though not at all so along the right bank. The question is often debated as to why, if water has something to do with the matter, the animals do not suffer. What makes them immune? The answer is, that they are not immune, only they are not investigated with sufficient care, for cases are reported of dogs, cats, goats, and sheep being affected. It may be that the goiter-producing substance is a ferment or something similar, and the plan used by Woaker of England rested on the giving of hydrofluoric acid, well diluted, thirty drops three times a day. While goiter may or may not be amenable to treatment; while surgical and medical treatment may both be had; and while partisans of both treatments may be found to attack all treatment, yet this much is stated here, if any patient is put upon boiled water, upon cod liver oil and upon orange juice, the chance for success of either treatment or any treatment, will become brighter at once.

The Regulation of the Composition of the Blood.—H. Hirschfeld in a lecture considers this subject in general, as well as a separate consideration of the various elements composing the blood from the viewpoint of the mechanism of their quantitative regulation. The writer insists too lengthily on elementary questions, but there are some interesting remarks to be found relating to recent data acquired in the domain of the genesis and destruction of the blood cells. Erythrocytosis is dependent upon the partial tension of the atmospheric oxygen breathed, it is regulated by the action of the bone marrow and spleen. The latter viscus prepares the destruction of the red blood corpuscles which takes place in the liver while at the same time it inhibits their genesis in the bone marrow. The spleen appears to be an organ of repair of the entire ferric metabolism and above all as an economic agent in the struggle against the disappearance of iron. The writer also studies the influence of various endocrine organs over the maintenance of the leucocytic equilibrium. This certainly adapts itself to the conditions of life. Thus the diet during the war, with its excess of carbohydrates, appears to have increased the percentage of lymphocytes in many apparently well people.

Surgical Affections Due to Influenza.—Schmieden says that septic pleurisy of influenzal origin has a decided tendency to extend to the opposite pleura as well as to invade the pericardium and peritoneum. The peculiarity is due to the necrosing action of the bacteria when they are unusually virulent and an absence of fibrous tissue reaction. Tracheal ulcerations may give rise to mediastinal phlegmon and mediastinal emphysema for which a tracheotomy may sometimes be successful in saving the patient's life. Influenzal infection of the cervical lymph-nodes does not necessarily end in suppuration. Rarely an influenzal parotiditis may develop, requiring incision. Peritonitis may arise as an autonomous complication of influenza; influenzal appendicitis does not generally suppurate so that operation is not indicated. The same applies to influenzal cholecystitis. In the nervous complications (which are not surgical in nature) the writer refers to purulent meningitis. There is also a form of infantile spinal paralysis which is unquestionably due to influenza. In the limbs one meets with thrombophlebitis, serous or dry arthritis, and osteomyelitis. Abscesses of the soft structures predominate on the thorax and abdominal parietes. The connection between these various surgical affections and influenza must be made by the history of each individual case.

The Solar Treatment of Tuberculous Laryngitis.—E. Pachner relates some cases of this affection which were happily influenced by insolation of the larynx according to Sargo's method. Insolation is accomplished by means of mirrors, the patient being able to turn his back to the sun or remain reclining upon a lounge. The latter procedure has the advantage of tiring the patient less and permits of a more direct use of the rays.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Thirteenth Annual Meeting, Held in Syracuse, May 5, 6, 7, and 8, 1919.

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

Monday, May 5, 1919.

THE PRESIDENT, DR. THOMAS H. HALSTED, IN THE CHAIR.

President's Report.—Dr. THOMAS H. HALSTED submitted this report in which he stated that of the 5,000 physicians in New York State about 3,700, or 25 per cent., left their practice and homes for military service, while a still greater number gave a large part of their time to the work of medical examiners, and on advisory medical boards. This of course had resulted in a general confusion and much disturbance in medical practice, just as similar results had occurred in other professions and business. He had spent the early part of his term of office in France as head of the Medical Intelligence Bureau, and later as Field Director of the Medical Research and Intelligence Department of the American Red Cross of which Colonel Alexander Lambert was Chief. On account of this absence he was unable to perform that agreeable part of his work which took him to the District Branch meetings in the fall of the year. It happened, however, that owing to the widespread epidemic of influenza and the large number of members absent in military service the District Branch meetings were very sparsely attended. After paying tribute to the memory of Dr. Frank Van Fleet and Dr. W. Staunton Gleason, whose absence he said would be deeply felt at this meeting of the Society, and expressing appreciation of the effective work of the chairmen of the various standing committees, he discussed compulsory health insurance. He stated that for good and satisfactory reasons the Medical Society of the State of New York opposed the enactment of various bills providing for compulsory health insurance, beginning with the Mills Bill and ending with the Davenport-Donohue Bill of the present session. Governor Smith, in his inaugural address, had urged compulsory health insurance and the Davenport-Donohue bill had been favored by the American Association for Labor Legislation, the New York State Federation of Labor, the City Club, Consumers' League and other organizations, chiefly of women. This bill, as it was amended from time to time during the Session, became exceedingly dangerous to the welfare of the future health of the employees, whom the bill was designed to benefit, as well as to that class of professional men and women, physicians, dentists, and nurses, who were to render the service. Realizing the dangerous character of the bill and the powerful elements in support of it, in letters to the Presidents of the County Medical Societies, he had urged the importance of acquainting the profession with the menace of the bill and the necessity for their using every effort to block its passage in the Legislature. There was an immediate response throughout the State, and at public hearings 350 to 400 physicians came to Albany as delegates, nearly every county being represented, and Kings County sending about 50 delegates. This bill, as it existed in its amended form on March 19, 1919, if enacted, would bring about a demoralization and degradation of the medical profession and an interruption of the progress of medicine that it was simply appalling. If enacted, it would reduce the profession largely to practising that kind of medicine known as "Lodge Practice." It would have taken away from the individual patient the right to free choice of physicians and have handed over the practice of medicine among 80 per cent. or more of the population to the lowest bidder and tended to reduce the profession to a trade or business. While admitting that the Bill had many objectionable features, Senator Davenport disclaimed responsibility for many of these and insisted on a Compulsory Health Insurance Bill, and asked the medical profession to propose constructive criticism and suggestions such as it believed fair. The hearing showed the strength of the opposition of the united medical profession to the Bill but it also demonstrated the purpose of the powerful proponents of health insurance to persist in the enactment of such a measure. Since the hearing further amendments, showing some effect of their opposition to the bill as it was, were introduced. The bill had failed of passage this year but it seemed to him that the society owed it to itself to make a serious study of the question of Health Insurance this year, and be prepared to make constructive and practical suggestions as to a sane and workable bill. If they did not do so they could not expect to receive very respectful consideration in the future by those who were honest in their belief that compulsory health insurance was one of the measures making for the welfare of the people, and who were bound to use every influence to bring it about. The subject was the most important one now before the society, and should be discussed in a broadgauged way during this session of the House of Delegates.

For several years the Board of Regents of the Educational Department had been endeavoring to have a bill enacted requiring the annual registration of physicians, believing this necessary as a part of the plan to regulate the practice of medicine in this State. There had been opposition in the profession to the principle of annual registration, believing it unnecessary and an abridgment of its constitutional rights, a bothersome nuisance, and in principle wrong, and that it required the physicians themselves to pay the cost of protecting the public against unlicensed, ignorant and unprincipled quackery. There was much truth in this contention. On the other hand, the present law by which County Medical Societies were the prosecutors of illegal and unlicensed practitioners of medicine was entirely inadequate to accomplish its purpose. In the proposed amendment to the Medical Practice Act, it became the duty of the Attorney General to prosecute, and such penalties and fines were provided that it was believed that the State would soon be rid of all persons illegally practising medicine, because convictions could be obtained and would be enforced. The local County Society ceased to be prosecutor, and the State Board of Regents became responsible for the upholding of the law. They might be dubious of the effectiveness of the operation of the act had they not had a concrete example of the working of a similar law in the case of the dental profession. In the case of this sister profession a law practically identical with this new medical practice act had been in operation for two years and had given general satisfaction. A veterinary law of like nature was also meeting with the approval of the members of that profession. In addition to the requirement of annual registration the law provided for an extension of the course of medical study of from four years of seven months each to four years of eight months each. The medical profession was burdened with the necessity of making an annual registration in the case of the narcotic laws, both of the State and of the Federal Government. It was believed that arrangements could be made whereby one registration would take care of the two now required by the narcotic laws and this new one under the medical practice act. It might be that these registrations could be effected through the machinery of the county medical societies, in which case a great deal of objection to these numerous registrations would be removed. The matter was under discussion by the Board of Regents, and a report would probably be made during the meeting of the society. The Council in a meeting held in Albany on February 26, 1919, endorsed the act as proposed by the Education Department, and recommended its introduction into the legislature.

There would be submitted to the House of Delegates a plan for a Bureau of Medical Information. As things stood to-day the organized medical profession was without adequate and accurate information on almost any subject that affected the economic or business side of the profession. On scientific questions they were all interested and tried to be informed. Many of the new laws were socialistic or paternalistic, and if enacted would change fundamentally the present relation of the profession to the public, to the

patient, and to each other. These laws would doubtless, many of them, be a step in real progress and should be welcomed. If we were to share in the benefit that would accrue to all, it was essential that they should be armed with the knowledge and information gleaned from the operation of these laws in other countries or states so that they could assist in their construction, opposing when opposition was needed, but fortified by facts so that they knew what they wanted, why they wanted it, and how to go about to get it. Such a bureau would require an office, executive officer, librarian, and stenographers, and would cost a considerable amount of money annually for its maintenance if it was to be of any value at all. It would be a great clearing house for all kinds of information that should be available not only to the organized profession but to the individual physician. He hoped the members of the society would concur in the recommendations favoring the establishment of such a Bureau of Medical Intelligence. The present Legislative Committee of the Society consisted of a Chairman and the chairmen of all the legislative committees of the county societies, an unwieldy committee of sixty men, which never met in conference, and as a result it was a committee in name only, the actual committee consisting of one man. There was too much work and two much responsibility for any one man, therefore an amendment would be proposed, changing the Legislative Committee, so that it would consist of three members. This was simply a return to the method that had been employed successfully for so many years. Because of the growing importance of economic questions as it affected the medical profession and because the County and State Medical Societies were the official bodies, the County Medical Society should be the most important and attractive medical society in every community. Many cities and towns had a local Academy of Medicine which often met more frequently and was more largely attended than the County Medical Society. He renewed the advice of Dr. Martin Tinker, who, when president of this society, urged the merging of local medical societies into the county society whereby these county societies would be enormously strengthened in every way to the betterment of each individual member. Dr. Halsted presented a supplementary report recommending the appointment of a special committee, to be appointed by the President, to consider the subject of public health insurance and to report to the Council of the Society by next fall so that they would be in a position to act with wisdom on any legislation of this nature which might be brought up next winter.

This report was referred to the reference committee on officer's reports which approved the recommendation.

Report of the Secretary.—Dr. FLOYD M. CRANDALL presented this report which showed that the membership of the State Society on January 1, 1919, was 8,268; on January 1, 1918, it was 8,339. On January 1, 1907, it was 5,857, making an increase during these twelve years of 2,411 members, the membership in the society having increased more rapidly than the accessions to the profession. This report contained reference to the loss the society had sustained in the deaths of Dr. W. Staunton Gleason and Dr. Frank Van Fleet. As an appreciation of Dr. Gleason, Dr. Crandall said he thought nothing could be more fitting that his own words on the death of Dr. Wisner R. Townsend: "Paramount to rules and orders, and rising high above business considerations is the tribute we owe to the memory of our late Secretary, the man, and the physian, Dr. Wisner R. Townsend. Encomiums are meaningless to you, his friends, for it was the little unremembered acts of devotion that bound him to you. His winsome personality and adaptability placed him in close touch with our entire membership. Out of the depths of our appreciation we place this laurel wreath of affection to his memory in the archives of this Society."

In appreciation of Dr. Van Fleet, he said in part: "The death of Dr. Van Fleet, Treasurer of the State Medical Society, has brought sorrow to physicians the length and breadth of the State. His friends were many, for to know him was to be his friend and hold him in honor. One of the most certain guarantees of character is to be held in honor most by those who know one best. This test Dr. Van Fleet fulfilled. He was held in high esteem in his own county, and served its Society up to its highest office. In his profession he stood in the first ranks, and in his specialty was second to none. He was a surgeon in the Eye Department of the Manhattan Eye, Ear and Throat Hospital, Chairman of the Board of Surgeons, and for many years Executive Surgeon. During his last months he devoted much thought and labor to ameliorating the sad condition of soldiers blinded in the fields and trenches of France and Flanders. He had for some time been in failing health, but with heroic spirit continued at his work and died in harness. His was a useful and faithful life. He left a great heritage, the memory of a well-spent life and an upright character, and to his son he left an honorable and untarnished name."

Report of Committee on Publication.—Dr. S. W. S. TOMS of Nyack, submitted in this report, which showed that the *Journal* had been issued regularly, the edition being about the same as 1917. The cost had been slightly less than the preceding year. In order to meet the problems confronting all publishers during the early part of last year, the Directory had published only the data of physicians in New York State, New Jersey, and Connecticut. By omitting the lists of hospitals, dispensaries, societies, examiners in lunacy, board of health notes, etc., they had saved the Society about $550.

Report of Committee on Finance.—Dr. HENRY LYLE WINTER of Cornwall submitted this report. The accounts showed a small deficit, $835, for the year 1918, due to the abnormal conditions which made a decrease in the usual number of new members of over three hundred. Taking the amounts received and expended from 1906 to 1918, there had been an excess of income of $4,121.70.

Report of Committee on Scientific Work.—Dr. PARKER SYMS, of New York, presented this report which outlined the work in connection with the preparation of the scientific program. The policy of the committee had been to maintain as far as possible the Section idea. It was the sense of the Committee that the holding of section meetings in the various specialties was a distinct advance in the method of conducting the meetings of the Society.

Report of Committee on Legislation.—Dr. JAMES F. ROONEY, of Albany, Acting Chairman, submitted this report. He stated that since having assumed the work of this committee on February 27, 1919, the bills introduced into the Legislature might be divided into four classes: 1. Those affecting the medical profession, especially as regards medical education. 2. Those relating to Public Health and administrative Public Health policies. 3. Those relating to licensure of various cults. 4. Those relating to so-called "Social Insurance." In the first class the most important bill was that providing for the annual registration of physicians, which was now in the order of third reading in the Assembly. This bill had the support of the Educational Department of the State of New York and of the Health Department of the State, and if previous experience with a similar bill affecting the dental profession was any criterion, would do more to save the public from imposition by quacks and impostors than any other measure. Several other bills coming under this class either were not reported or were killed in committee. Under the second heading were comprised the bills affecting especially the newly instituted department of narcotic drug control. Upon these bills the medical society took no stand because of the fact that it was unimportant to the profession how this law would be administered; it was purely a matter of administrative State policy. A bill similar to the New York City ordinance, requiring registration by the Department of Health of all proprietary medicines was not reported from committee. A similar fate befell another bill which purported to make the giving and delivering of any narcotic drug to a child under the age of sixteen a felony instead of, as it is at present, a misdemeanor. This bill was supported by the Society but was opposed by the pharmacists, and has not been reported. Under the third heading falls the so-called "Chiropractic Bill," which was defeated in the Judiciary Committee by a vote of eight to four. The most important measure in the fourth group

was the Compulsory Health Insurance Bill. A very subtle and continuous propaganda was being carried on to create in the mind of the people the impression that legislation of this sort was inevitable. In the opinion of the speaker this attitude was not true; the passage of this sort of legislation was not inevitable.. The proponents of this legislation realized that they must pass their legislation at this session, because it was not impossible that the reaction against all forms of socialism and communism, of which this was the second step in the entering wedge, would be utterly rejected by the American people. He felt still convinced that the only attitude for the medical profession to take was that of "no compromise." This did not preclude the taking of proper precautions for the protection of the public and secondarily of the medical profession in the event of this bill's passage. The taking of these precautions should not in any way affect the general attitude of the Society in opposing the legislation on the broad principle of lack of proof, either of its necessity in America or of accomplishment of the purpose which it pretends to accomplish. In a supplementary report Dr. Rooney stated that the Medical Registration bill was defeated by Mr. Ferron, of Syracuse, who was an advocate of the Chiropractic Bill which, since the writing of the report, had been defeated.

Report of Special Committee on the Establishment of a Bureau of Legislative Information.—Dr. GEORGE W. KOSMAK submitted this report, the other members of the committee being Dr. Henry Lyle Winter and Joshua M. Van Cott, which consisted in a scheme for the creation of a Research Bureau of Public Health Legislation. The report pointed out that the ability of most medical men properly to analyze or comprehend the many medical bills emanating from the Legislature was doubtful. This required special training, particularly legal. The lack of effective opposition to inimical legislation was becoming increasingly evident during recent years. The admission also had to be made that the legislature could not be made to feel the weight of the combined medical opinion of the State because there was no well-defined procedure or agency by which physicians could be interested directly either as individuals or through their county societies, nor any satisfactory way by which their sentiments could be transmitted through a central agency to those who should be reached by these opinions. The interests of the profession in this State required that some step be taken to meet the situation. It was believed that a centrally organized bureau, properly equipped and officered, would best meet the demands of the situation. Although a departure from custom, the increasing importance of public health and allied legislation would seem to justify a reform in their previous methods of studying legislation, so that physicians as a class might become better acquainted with the subject matter of proposed legislative enactments which might be often of vital interest to them and could, moreover, make the weight of their opinions felt when necessary. It was believed that a movement of this kind could be appropriately inaugurated by the representative medical societies of the State. Two serious difficulties at once become evident; first, the odium attached to a paid legislative agent or "lobbyist," and, second, the prohibitive expense. The committee believed that both of these objections could be satisfactorily met and a working organization created which would be in position to assume the burden and responsibilities of watching medical legislation for the benefit of the entire profession of the State. It was recommended to have the office of the bureau in the city of New York and preferably in the New York Academy of Medicine. The functions of the bureau were as follows:

"To keep on file a ready reference index of all laws and reference books on laws concerning public health, medical practice and preventive medicine in the civilized world and where they can be obtained. File of important proposed laws in other States of the Union which may have a bearing on bills introduced or to be introduced in the current session of the New York State Legislature. File of bills to be obtained as soon as introduced in the Legislature of New York or Congress, to be promptly studied by the counsel and a brief written on the same for argument at hearings before committees of legislators or the Governor if necessary. In this way those interested in the proposed legislation can easily completely inform themselves of exactly what the law intends, what existing laws are enhanced or violated, and what the experience has been with a similar law in other States or countries. Perfecting machinery for the construction of laws in the interest of public health and preventive medicine and for the repeal of existing inimical laws or sections of laws. Bureau of information concerning existing public health laws available to societies, legislators and others properly interested in the welfare of public health. Press agency for dignified propaganda in the name of the bureau in the interest of proposed public health legislation or in opposition of proposed laws detrimental to public health and preventive medicine. Such other activities within the scope of the bureau as may suggest themselves."

Report of Committee on Medical Economics.—Dr. HENRY LYLE WINTER submitted this report, which stated that the committee had continued to pursue the study of Health Insurance and State Medicine during the past year. It was apparent from the manner in which the health insurance bills were amended by their proponents that the costs of the administration of the medical provisions were under constant consideration, hence the committee had thought it advisable to provide itself with first hand cost data. As the result of information obtained from questionnaires sent out it was the opinion of the committee that the medical provisions of all health insurance bills so far presented failed to provide for proper medical care of the sick and efficient supervision of the public health, and did not safeguard the interests of the medical profession. They advised therefore the continued and united opposition of the society to these measures. In order that the attitude of the society should be most influential a Statewide effort to increase membership was advised. The committee found that the complexity of social conditions incident to the rapid industrial growth through which the country was passing had produced a necessity in some quarters for specific changes in medical practice and the application of public health measures. The proponents of health insurance proposed to meet these conditions through that medium. This committee was satisfied that the desired conditions could not be met by the medical provisions of a health insurance law. They believed that it could be done through the medium of State medicine, which should include the establishment of diagnostic clinics and laboratories at convenient points, and also a system of investigation and correction applied through the medium of the State Health Department or some other central body which would work effectively for the prevention of disease. That some plan satisfactory to the whole profession might be evolved the committee advised the establishment of a Committee on Economics in each county society to cooperate with the State Committee.

Report of Committee on Public Health and Medical Education.—Dr. JOSHUA VAN COTT of Brooklyn submitted this report, which stated that the committee had studied the Davenport Donohue bill for establishing compulsory health insurance in the State of New York and that it was opposed to the bill. It was claimed that the amendments to the bill offered the necessary protection and representation for physicians. But close analysis of the amended portions of the bill they felt did not sustain these contentions. The bill as a whole created a machinery which, in its organization and administration, was under the danger of political influence, and it was difficult to see how, under its provisions, its purpose could be successfully realized. If compulsory health insurance was to become a law, unless the bill were so drawn as to be measurably acceptable to the medical profession of the State of New York, our young men would go elsewhere to study and practise medicine. The time was not yet ripe for such legislation, but when it did arrive some plan should be evolved which would make it possible for self-respecting physicians of the best type to undertake the work and receive adequate compensation for it. The committee approved Assembly Bill 1276, 1693, Int. 1145, introduced by Mr. Kenyon, to amend the Public Health Law in relation to the practice of medicine.

Report of Special Committee to Consider Economic Methods of Caring for the Public Health.—Dr. F. PARK LEWIS of Buffalo submitted this report, which stated

that the purpose of modern medicine was to limit as far as possible all avoidable disease and to restore as quickly as might be the sick to health. All preventive measures and all scientific treatment were based on early and accurate diagnosis. In order to reach an early and accurate diagnosis the services of a group of trained workers was necessary. A most urgent problem, therefore, was to determine how they might be secured. This committee suggested that the remedy would seem to lie in the establishment of numerous easily accessible diagnostic clinics readily available through the medium of the family physician and safeguarding not only the physical welfare of the patient but the economic protection as well of all affected by the arrangement, including the patient, the family physician and the consultants. The proper place for such clinics would seem to be in the public hospitals, which were already equipped for such work and whose staffs could be augmented as necessity requires. It was evident that this would demand a revision of the plan of work as now carried out in nearly every hospital in the country. The subject was one having many sides. It concerned not only the physicians and the people of New York State but those of the whole country. It was recommended, therefore, that the delegates of the New York State Medical Society of the American Medical Association be directed to present this important matter to the house of delegates of the American Medical Association with a request that it be considered by that body in order that some method might be adopted by which group diagnosis should be secured which would be equitable alike to the patient, to the physician, and to the State. All of the foregoing reports containing recommendations were referred to the reference committee.

Report of Special Committee on Drug Addiction.—Dr. EDWARD B. ANGELL submitted this report, in which the conclusion was reached that the present act, which went into effect on February 1, 1919, was less complex and burdensome to the physician, and as it stood to-day less exacting in its requirements than the Federal law. Perhaps for the general practitioner the most annoying requirement of the act was that the order to the manufacturer or wholesale dealer be issued in triplicate on an official blank. The Federal law already required a duplicate order and it did seem a useless sort of tautology to require a physician to write five times for a small package of ¼ gr. tablets of morphine. However, this was an incident to be forgotten. The committee was, furthermore, of the opinion that drug addiction should be treated in a proper institution.

On motion this report was referred to a special committee appointed by the president.

Report of the Counsel.—JAMES TAYLOR LEWIS, Esq., submitted this report, which outlined the work he had done for the society during the past year. It showed that not a single case tried during the year was lost, and not a case was settled. Twenty-one cases had been finally disposed of during the year. Thirty-two new actions were brought during the year. One case, a sponge case, was lost in trial court in 1915. This case was appealed to the Supreme Court, Appellate Division, Second Department, and there the judgment was affirmed. From there the case was appealed to the Court of Appeals of this State, and the judgment originally rendered by the jury was affirmed together with the costs and interest. It was extremely regrettable that our State court of last resort accorded the profession no added information as to what rule should govern, if any, other than that laid down in the case of Pike vs. Honsinger, which had furnished for more than twenty years the exact measure of the doctor's responsibility. Other State courts had furnished the profession valuable suggestions in so-called sponge cases and laid down most important dicta. He knew no more about the responsibility of a nurse, an interne, or the equipment of a hospital, whether it be good or bad, or whether the hospital and not the operator was responsible for miscounts, dirty instruments, or bad equipment leading to an unfortunate result, than he did before this case was taken to the Court of Appeals. The society should be advised that he had been informed that some of the insurance companies had abandoned the defense of doctors because of losses in the trial of their cases. There must be but one explanation of this if it were true, and that was that when a jury learned that a doctor was indemnified it was very willing to bring a verdict which held the insurance company responsible, but incidentally ruined the doctor's reputation. A doctor's reputation seemed to be a matter of small moment to a jury when they knew that an insurance company was really the defendant. The State Dental Society had not made progress in the defense of its members, and he felt convinced that their efforts had been hampered by the importunities of insurance companies' runners who had interfered with the society's honest effort. Every member of the society had heard him repeatedly express his feeling with reference to physicians taking insurance policies indemnifying them against loss for negligence. These policies were a very serious menace. The doctors who held them must remember that the State Society might not defend them, and they must choose between the attorney for the insurance company and the wholehearted defense of the State Medical Society should they be sued. Since his last report the Whitney bill had been passed. He did not believe that one doctor in a hundred was familiar with this law, and he was also convinced that 50 per cent. of the profession violated the law every day. He had thought that the Harrison law was unconstitutional, but of the eight Federal Supreme Court judges five had declared it constitutional, while three declared it unconstitutional. He thought the Whitney bill was unconstitutional; but whether constitutional or not it had been enacted and must be obeyed. Physicians would have to study these two laws together and try to comply with them. A record must be kept of every 1/16 grain of morphine prescribed. The law requiring doctors to register every case of contagious disease or venereal disease must be watched. Every member should have these laws before him lest he be charged with a crime in failing to register names. He believed this law was also unconstitutional.

Address on Health Insurance.—Senator DAVENPORT delivered this address, in which he said that he would like to have all parties interested in health insurance bring to the discussion of the subject the facts so that they might know just what should be done in the matter. It had always been his policy, he said, to bring a controversy out into the open, for he thought that very often when that was done the heat passed off and the light began to appear. He would not be in favor of compulsory health insurance if he did not believe that it would benefit every group concerned, the employer, the employee, and the physician. He told the history of the bill and of his endeavor to get suggestions from all parties concerned. Politically he said he was an anti-Bolshevist liberal of the Roosevelt style. He believed that the greatest menace of the present time came from Moscow; if necessary that menace should be dealt with by the machine gun, but there was another way of dealing with it, and that was by doing away with the sources that gave rise to Bolshevism by trying to make this world a better and a happier place in which to live. The greatest danger from Bolshevism was not from the standpoint of disorder, for that could be dealt with by force, but from the Bolshevist philosophy, the idea that the man of genius, the man of initiative, the inventor, were worth nothing. He was interested in destroying the Bolshevist philosophy, and he saw in health insurances a point at which capital and labor could come together. It was not wise to oppose all liberalism; one must learn to distinguish between liberalism and Bolshevism. The best barrier to Bolshevism was not capital, but a great, strong contented working class, especially the higher layers of the working class. He had found a strong sentiment in favor of some form of protection against sickness among the laboring classes. It seemed to him that the present treatment of illness was too individualistic; people were too apt to neglect consulting a doctor when they should do so or to put off consulting him much longer than they should do. While he did not feel that the blame could be laid at the door of the medical profession, the fact remained that the people were not getting the most perfect treatment under the individualistic system. Evidence of this was furnished by the large number of men rejected by the draft boards; about 40 per cent. of the men between the ages

of twenty-one and thirty-one coming before the draft boards were found unfit for service. Investigation had shown that there was a vast amount of illness among the industrial population that was not adequately cared for. There was here a great amount of work to be done. There were two ways of doing it, either by reorganizing and extending our health department service or by some form of health insurance. At the present time the burden of illness fell on certain persons, or certain families, and his idea was to distribute this burden. Illness was much like fire or accident in that it was a matter of chance and the burden could be distributed just as it was in fire or accident. The old theory of the survival of the fittest had been outgrown and we had found that it was by developing the social processes that the finest kind of initiative was developed. He thought that health insurance would better the condition of the medical profession and the plan would leave the profession in a very flexible position. A family would select its own physician. The fund was to pay the doctor a standard fee and if the fee of any individual physician was above that standard the family employing the physician was to pay the difference between the standard fee and the one asked by that particular physician. He referred to the report of the Insurance Acts Committee of the British Medical Association as showing how compulsory health insurance had worked out in England, where the attitude of the opponents of compulsory health insurance had entirely changed during the past few years. He presented arguments to show how compulsory health insurance would aid in sickness prevention, and said that he was especially anxious that the medical profession should be associated with the development of a system of health insurance, for he felt that physicians would be better off under a properly organized system of compulsory health insurance than they were under existing conditions, both as regarded prestige and finances. He asked that in this work he might have the cooperation of a group of men from the Medical Society of the State of New York.

Tuesday, May 6, 1919.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Grant C. Madill of Ogdensburg; *First Vice-President*, Dr. Dwight H. Murray of Syracuse; *Second Vice-President*, Dr. William M. Dunning of New York; *Third Vice-President*, Dr. George W. Cottis of Jamestown; *Secretary*, Dr. Floyd M. Crandall of New York; *Assistant Secretary*, Dr. Edward Livingston Hunt of New York; *Treasurer*, Dr. Harlow Brooks of New York; *Assistant Treasurer*, Dr. Thomas C. Chalmers of Forest Hills, Queens, N. Y.; *Chairman of Committee on Scientific Work*, Dr. Parker Syms of New York; *Chairman of Committee on Public Health and Medical Education*, Dr. Joshua M. Van Cott of Brooklyn; *Chairman of Committee on Legislation*, Dr. J. Richard Kevin of Brooklyn; *Chairman of Committee on Medical Economics*, Dr. Henry Lyle Winter of Cornwall; *Chairman of Committee on Medical Research*, Dr. Frederic E. Sondern of New York; *Committee on Prize Essays*, Dr. Albert Vander Veer of Albany, Dr. Edward D. Fisher of New York, and Dr. Charles G. Stockton of Buffalo; *Delegates to the American Medical Association to serve two years*, Drs. James F. Rooney of Albany, William Francis Campbell of Brooklyn, Thomas H. Halsted of Syracuse, George D. Stewart of New York, Floyd M. Crandall of New York, and E. Eliot Harris of New York; *Alternates*, Drs. William S. Gottheil of New York, James F. McKernon of New York, Sylvester J. McNamara of Brooklyn, G. W. Wende of Buffalo, T. C. Chalmers of Queens, N. Y., and G. S. Towne of Saratoga Springs.

It was voted to hold the next annual meeting in New York City, at a date to be decided upon by the Council.

Amendments to Constitution and By-Laws.—An amendment of Article IV of the Constitution, submitted at the annual meeting in 1918, which provided for representation of the society in the House of Delegates on the basis of actual active membership of the county societies instead of by assembly districts, was brought up for consideration. The House resolved itself into a committee of the whole to debate the proposed amendment and after lengthy discussion reported adversely on the amendment. Other amendments adopted provided that the annual meetings of the society should be held the first week in May; that the Committee on Legislation should consist of a chairman and two other members; that each district-branch might adopt a constitution and by-laws provided that such was first approved by the Council of the Society, except that it should have a free hand in dealing with members addicted to practices considered not strictly professional in their method of practice.

Resolutions.—Among the resolutions and recommendations introduced, upon which action was delayed until the next meeting, was a recommendation by Dr. Dwight H. Murray that the House of Delegates amend the Constitution and By-Laws so as to provide for the election of a speaker and vice-speaker for the House and that a section be added to the Constitution defining their duties. Dr. James F. Rooney introduced resolutions approving of a survey of the State to be made by the State Department of Health and the State Industrial Commission, with the object of ascertaining the conditions under which the industrial population of the State were living and working, having as its purpose the improvement of such conditions. This resolution was adopted. Dr. Malcolm C. Rose introduced resolutions providing for the establishment of a Bureau of Location in the office of the State Society, which would be helpful to general practitioners and specialists who were looking for locations and for communities in need of physicians. It had happened during the past year that there were communities which were without medical service. Such a step would also be an advantage to the Society in increasing its membership, since physicians who were assisted in selecting a location would be glad to lend their support to the Society. Provision was also made for the cooperation of the county societies in the working out of such a plan. These resolutions were referred to the Council for action. Resolutions instructing the delegates to the American Medical Association to express the sentiment of the Society as unqualifiedly opposed to compulsory health insurance were adopted. A special committee to consider the question of compulsory health insurance was appointed, which was to report to a special meeting of the House of Delegates to be convened in the fall on a date to be decided upon by the Council. The Erie County Medical Society presented resolutions favoring the establishment of a group of diagnostic clinics throughout the State if adequate and continuous control of their organization and management by the medical profession could be fully assured, as they recognized the necessity of further action which would improve the care of the sick and further the prevention of disease. These resolutions were referred to the Council.

OPENING MEETING.

Tuesday Evening, May 6, 1919.

THE PRESIDENT, DR. THOMAS H. HALSTED IN THE CHAIR.

Invocation.—The Rev. Dr. McGUINNIS of Syracuse opened the meeting with an invocation.

Address of Welcome.—Dr. DWIGHT H. MURRAY of Syracuse, chairman of the Committee on Arrangements, said that it was with pride that the local branch of the Medical Society of the State of New York welcomed the parent organization. This meeting was of especial significance because it was the first Victory Meeting of the Society, when it took pleasure in welcoming home those of its members who had been in the service of their country. The war had given them another opportunity to prove that the medical profession, with little or no thought for itself, always stood ready to give its services for the nation or the individual.

Address of Welcome.—Hon. WALTER R. STONE, Mayor of the City of Syracuse, welcomed the members and to express the sentiment of the Society as unqualifiedly guests of the Society in behalf of Syracuse. He said that the City of Syracuse was impressed with the importance of having the Medical Society of New York meet here. They were deeply impressed with the fact that the scientific discussions that would take place would be of inestimable benefit both to the medical pro-

fession of the city and to the people. The people were awake to the value of the work that the medical profession was doing, as was demonstrated by the fact that they had recently established a Department of Health in the City of Syracuse instead of having the public health work cared for by other city department.
